ARCHIVES OF DISEASE IN CHILDHOOD

CUK-H05058-3-P025130

The Journal of the British Paediatric Association

(3)

Original Articles

Intellectual performance in children after circulatory arrest with profound hypothermia in infancy *D. F. Dickinson and J. E. Sambrooks* 1

Congenital complete heart block in the newborn associated with maternal systemic lupus erythematosus and other connective tissue disorders *J. D. Hardy, S. Solomon, G. S. Banwell, R. Beach, V. Wright, and F. M. Howard* 7

Behavioural deviance in children with early treated phenylketonuria *J. E. Stevenson, Janet Hawcroft, Mary Lobascher, Isabel Smith, O. H. Wolff, and P. J. Graham* 14

Intestinal bile salts in cystic fibrosis: studies in the patient and experimental animal *J. T. Harries, D. P. R. Muller, J. P. K. McCollum, A. Lipson, E. Roma, and A. P. Norman* 19

Complete deficiency of adenine phosphoribosyltransferase: a third case presenting as renal stones in a young child *T. M. Barratt, H. A. Simmonds, J. S. Cameron, C. F. Potter, G. A. Rose, D. G. Arkell, and D. I. Williams* 25

The lungs in congenital bilateral renal agenesis and dysplasia *Alison Hislop, E. Hey, and Lynne Reid* 32

Cows' milk protein-sensitive enteropathy: an important contributing cause of secondary sugar intolerance in young infants with acute infective enteritis *N. Iyngkaran, K. Davis, M. J. Robinson, C. G. Boey, E. Sumithran, M. Yadav, S. K. Lam, and S. D. Puthucheary* 39

Prognostic factors in acute meningococcaemia *L. S. Lewis* 44

Aortic arch interruption presenting with absence of all limb pulses *G. P. Sharratt, R. Leanage, J. L. Monro, and E. A. Shinebourne* 49

Housing and mothering *M. Pollak* 54

Conservative care of the newborn baby *T. H. Hughes-Davies* 59

Plasma somatomedin activity in protein calorie malnutrition *P. S. Mohan and K. S. Jaya Rao* 62

Isoniazid liver injury during chemoprophylaxis in children *P. Spyridis, C. Sinaniotis, I. Papadea, L. Oreopoulos, S. Hadjiyiannis, and C. Papadatos* 65

Short reports

Delayed diagnosis of congenital anal stenosis *E. M. Kiely, R. Chopra, and J. J. Corkery* 68

Acute anuric renal failure in an infant with systemic candidiasis *J. Z. Heckmatt, S. R. Meadow, and C. K. Anderson* 70

Leukaemic hypopyon in acute lymphoblastic leukaemia after interruption of treatment *G. Masera, V. Carnelli, C. Uderzo, C. Toselli, F. Lasagni, and E. Lambertenghi* 73

Reye's syndrome associated with respiratory syncytial virus infection *N. Griffin, J. W. Keeling, and A. H. Tomlinson* 74

Chloramphenicol and phenobarbitone—a drug interaction *R. A. Bloxham, G. M. Durbin, T. Johnson, and M. H. Winterborn* 76

Food allergy: response to treatment with sodium cromoglycate *J. B. G. Watson and J. Timmins* 77

Technical Editor: Jennifer Orton

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42**, 109; 1973, **48**, 751).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged.
(11) References in the text. Papers with one or two authors: name author(s) on each occasion the paper is cited with year of publication in parentheses. Papers with more than two authors: use—*et al.* in each citation.
(12) References to be listed alphabetically with full title of article or book; title of journal to be given in full, first *and* last page numbers of journal articles to be given.
(13) Summary to be typed on a separate sheet; and it should say what was done, and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate from January 1979 will be £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

Copyright © 1979 by *Archives of Disease in Childhood.* This publication is copyright under the Berne Convention and the International Copyright Convention. All rights reserved. Apart from any relaxations permitted under national copyright laws, no part of this publication may be reproduced, stored in a retrieval system, or transmitted in any form or by any means without the prior permission of the copyright owners. Permission is not, however, required to copy abstracts of papers or of articles on condition that a full reference to the source is shown. Multiple copying of the contents of the publication without permission is always illegal.

No. 1 January 1979

Original articles

Intellectual performance in children after circulatory arrest with profound hypothermia in infancy. D. F. Dickinson and J. E. Sambrooks 1
Congenital complete heart block in the newborn associated with maternal systemic lupus erythematosus and other connective tissue disorders. J. D. Hardy, S. Solomon, G. S. Banwell, R. Beach, V. Wright, and F. M. Howard 7
Behavioural deviance in children with early treated phenylketonuria. J. E. Stevenson, J. Hawcroft, M. Lobascher, I. Smith, O. H. Wolff, and P. J. Graham 14
Intestinal bile salts in cystic fibrosis: studies in the patient and experimental animal. J. T. Harries, D. P. R. Muller, J. P. K. McCollum, A. Lipson, E. Roma, and A. P. Norman 19
Complete deficiency of adenine phosphoribosyltransferase: a third case presenting as renal stones in a young child. T. M. Barratt, H. A. Simmonds, J. S. Cameron, C. F. Potter, G. A. Rose, D. G. Arkell, and D. I. Williams 25
The lungs in congenital bilateral renal agenesis and dysplasia. A. Hislop, E. Hey, and L. Reid 32
Cows' milk protein-sensitive enteropathy: an important contributing cause of secondary sugar intolerance in young infants with acute infective enteritis. N. Iyngkaran, K. Davis, M. J. Robinson, C. G. Boey, E. Sumithran, M. Yadav, S. K. Lam, and S. D. Puthucheary 39
Prognostic factors in acute meningococcaemia. L. S. Lewis 44
Aortic arch interruption presenting with absence of all limb pulses. G. P. Sharratt, R. Leanage, J. L. Monro, and E. A. Shinebourne 49
Housing and mothering: their effects upon the developmental levels of 3-year-old children. M. Pollak 54
Conservative care of the newborn baby. T. H. Hughes-Davies 59
Plasma somatomedin activity in protein calorie malnutrition. P. S. Mohan and K. S. Jaya Rao 62
Isoniazid liver injury during chemoprophylaxis in children. P. Spyridis, C. Sinaniotis, I. Papadea, L. Oreopoulos, S. Hadjiyiannis, and C. Papadatos 65

Short reports

Delayed diagnosis of congenital anal stenosis. E. M. Kiely, R. Chopra, and J. J. Corkery 68
Acute anuric renal failure in an infant with systemic candidiasis. J. Z. Heckmatt, S. R. Meadow, and C. K. Anderson 70
Leukaemic hypopyon in acute lymphoblastic leukaemia after interruption of treatment. G. Masera, V. Carnelli, C. Uderzo, C. Toselli, F. Lasagni, and E. Lambertenghi 73
Reye's syndrome associated with respiratory syncytial virus infection. N. Griffin, J. W. Keeling, and A. H. Tomlinson 74
Chloramphenicol and phenobarbitone—a drug interaction. R. A. Bloxham, G. M. Durbin, T. Johnson, and M. H. Winterborn 76
Food allergy: response to treatment with sodium cromoglycate. J. B. G. Watson and J. Timmins 77
Correspondence 80
Book review 84

No. 2 February 1979

Original articles

Striatal degeneration in childhood. M. Erdohazi and P. Marshall 85
Screening for cystic fibrosis in the newborn by meconium analysis. H. C. Ryley, L. M. Neale, T. D. Brogan, and P. T. Bray 92
Curd and whey proteins in the nutrition of low birthweight babies. H. M. Berger, P. H. Scott, C. Kenward, P. Scott, and B. A. Wharton 98
Effect of tolazoline in severe hyaline membrane disease. N. McIntosh and R. O. Walters 105
Factors affecting neonatal jaundice. B. Wood, P. Culley, C. Roginski, J. Powell, and J. Waterhouse 111
Childhood asthma. A controlled trial of family psychotherapy. B. Lask and D. Matthew 116
Antigen-antibody complexes in the serum of patients with juvenile chronic arthritis. H. Moran, B. M. Ansell, J. F. Mowbray, R. J. Levinsky, and J. F. Soothill 120
Reduction of insulin dose on changing diabetic children from standard to monocomponent insulins. N. K. Griffin, M. A. Smith, and J. D. Baum 123
Interferon synthesis by human colostral leucocytes. J. W. M. Lawton, K. F. Shortridge, R. L. C. Wong, and M. H. Ng 127
Duodenal bile acids in infants with protracted diarrhoea. D. N. Challacombe, G. A. Brown, and S. Edkins 131
Familial partial trisomy of the long arm of chromosome 3 (3q). C. Fear and A. Briggs 135
Hepatic dysfunction in childhood malaria. A. Patwari, S. Aneja, A. M. Berry, and S. Ghosh 139

Short reports

Familial occurrence of omphalocele suggesting sex-linked inheritance. S. Havalad, H. Noblett, and B. D. Speidel 142
Nonaccidental poisoning in childhood. J. B. G. Watson, J. M. Davies, and J. L. P. Hunter 143
Quantitation of digital clubbing by shadowgram technique. D. Sinniah and A. Omar 145

No. 2 February 1979—*continued*

Fatal bleeding from gastric ulceration during first day of life—possible association with social stress. R. J. Pugh, R. W. Newton, and D. M. Piercy 146
Hepatomegaly due to self-induced hyperinsulinism. J. Asherov, M. Mimouni, I. Varsano, E. Lubin, and Z. Laron 148
Phenothiazine-induced dystonia associated with an increase in serum creatine phosphokinase. W. Y. Lui 150
Paediatric Pathology Society 152
Paediatric Research Society 160
Correspondence 166
Book reviews 168

No. 3 March 1979

Annotation

Genetic registers. M. E. Pembrey 169

Original articles

Results of a regional cord blood screening programme for detecting neonatal hypothyroidism. P. G. Walfish, J. Ginsberg, R. A. Rosenberg, and N. J. Howard 171
Response of term babies to a warm environment. N. Rutter and D. Hull 178
Clinical evaluation and comparison of the Infrasonde, Arteriosonde, and mercury sphygmomanometer in measurement of blood pressure in children. J. M. Savage, M. J. Dillon, and J. F. N. Taylor 184
Dosage schedule for intravenous aminophylline in apnoea of prematurity, based on pharmacokinetic studies. R. A. K. Jones and E. Baillie 190
Plasma xanthine levels in low birthweight infants treated or not treated with theophylline. J-L. Brazier, H. Renaud, B. Ribon, and B. L. Salle 194
Medulloblastoma—a changing prognosis? N. McIntosh 200
A controlled trial of cyclophosphamide and azathioprine in Nigerian children with the nephrotic syndrome and poorly selective proteinuria. A. Adeniyi, R. G. Hendrickse, and J. F. Soothill 204
Serum gastrin levels in hypertrophic pyloric stenosis of infancy: response to a gastrin secretion test. M. A. Hambourg, M. Mignon, C. Ricour, J. Accary, and D. Pellerin 208
Transpyloric feeding in the very low birthweight (1500 g and below) infant: one year's experience in an intensive care neonatal unit. I. Beddis and S. McKenzie 213
Lysozyme in the tears of newborn babies. P. C. Etches, F. Leahy, D. Harris, and J. D. Baum 218
Lomotil poisoning in children. J. A. Curtis and K. M. Goel 222
Foot length—a new and potentially useful measurement in the neonate. D. K. James, E. H. Dryburgh, and M. L. Chiswick 226

Short reports

Mycoplasma hominis: a cause of neonatal meningitis. M. Gewitz, R. Dinwiddie, L. Rees, O. Volikas, T. Yuille, B. O'Connell, and W. C. Marshall 231
A clinical comparison of beclomethasone dipropionate delivered by pressurised aerosol and as a powder from a rotahaler. A. T. Edmunds, S. McKenzie, M. Tooley, and S. Godfrey 233
Cefuroxime plasma and CSF levels in children with meningitis. J. A. Kuzemko and S. R. Walker 235
Idiopathic hypoparathyroidism with extrapyramidal and myopathic features. R. O. Walters 236
Half life of theophylline in the preterm baby with apnoeic attacks. D. M. King, A. F. Heeley, and J. A. Kuzemko 238
Correspondence 240
Book reviews 246
Referees 248

No. 4 April 1979

Review article

Recognition and management of children with increased lead absorption. J. J. Chisolm, Jr and D. Barltrop 249

Annotations

Red cell aplasia in children. B. P. Alter and D. G. Nathan 263
A better deal for newborns with congenital heart disease. F. Macartney 268

Original articles

Diagnosis and management of folate deficiency in low birthweight infants. M. K. Strelling, D. G. Blackledge, and H. B. Goodall 271
New technique for servo-control of arterial oxygen tension in preterm infants. I. R. Beddis, P. Collins, N. M. Levy, S. Godfrey, and M. Silverman 278

No. 4 April 1979—*continued*

Structural heart disease in the newborn: changing profile—comparison of 1975 with 1965. T. Izukawa, H. C. Mulholland, R. D. Rowe, D. H. Cook, K. R. Bloom, G. A. Trusler, W. G. Williams, and G. W. Chance 281
Seroepidemiology of cytomegalovirus infections during the first years of life in urban communities. N. Cabau, M. D. Labadie, C. Vesin, J. Feingold, and A. Boué 285
The spread of Coxsackie B1 infection. T. W. Hoskins, J. R. Davies, A. J. Smith, K. Collingham, and R. N. Chamberlain 291
Glycosylated haemoglobin levels in children with diabetes mellitus. M. L. Williams and D. C. L. Savage 295
Drug metabolism in malnourished children: a study with antipyrine. M. Homeida, Z. A. Karrar, and C. J. C. Roberts 299

Personal practice

Mourning by the family after a stillbirth or neonatal death. E. Lewis 303

Short reports

Improved accuracy of continuous measurement of arterial oxygen tension in sick newborn infants: criteria for reading and recalibrating the electrode. A. R. Wilkinson, R. H. Phibbs, and G. A. Gregory 307
Haemorrhage responsive to vitamin K in a 6-week-old infant. A. M. B. Minford and O. B. Eden 310
Cervical lymphadenitis in childhood due to mycobacteria of the Fortuitum group. M. J. Rivron, E. A. Hughes, J. R. Sibert, and P. A. Jenkins 312
Progressive hypogammaglobulinaemia in a child born to a mother with Hodgkin's disease. D. I. K. Evans and J. L. Burn 313
Intrapartum sensitisation of human infants to the Rhesus-D antigen. C. M. Stern 315
Fetal growth and parental consanguinity. J. R. Sibert, M. Jadhav, and S. G. Inbaraj 317
European Society for Paediatric Nephrology 320
Correspondence 326
Book reviews 328

No. 5 May 1979

Annotation

Diagnosis of malignant hyperphenylalaninaemia. D. M. Danks, R. G. H. Cotton, and P. Schlesinger 329

Original articles

Neonatal form of dystrophia myotonica: five cases in preterm babies and a review of earlier reports. R. G. Pearse and C. J. Höweler 331
A year's experience of the rotavirus syndrome and its association with respiratory illness. H. M. Lewis, J. V. Parry, H. A. Davies, R. P. Parry, A. Mott, R. R. Dourmashkin, P. J. Sanderson, D. A. J. Tyrrell, and H. B. Valman 339
Plasma 17OH-progesterone concentrations in newborn infants. I. A. Hughes, D. Riad-Fahmy, and K. Griffiths 347
Continuing need for mineralocorticoid therapy in salt-losing congenital adrenal hyperplasia. I. A. Hughes, A. Wilton, C. A. Lole, and O. P. Gray 350
Effects of pethidine and its antagonists on the newborn. J. E. H. Brice, T. A. Moreland, and C. H. M. Walker 356
Creatine phosphokinase levels in the newborn and their use in screening for Duchenne muscular dystrophy. L. M. Drummond 362
Serum 25-hydroxy-vitamin D in hepatobiliary disease in infancy. A. Kobayashi, S. Kawai, M. Ohkubo, and Y. Ohbe 367
Relationship between urinary and blood glucose in diabetic children. N. K. Griffin, M. A. Smith, P. A. Jenkins, G. Werther, and J. D. Baum 371
Iron deficiency in children with coeliac disease on treatment with gluten-free diet: role of intestinal blood loss. I. Kosnai, P. Kuitunen, and M. A. Siimes 375
Absorption of chlorhexidine from the intact skin of newborn infants. J. Cowen, S. H. Ellis, and J. McAinsh 379
Infective pericarditis in Nigerian children. F. Jaiyesimi, A. A. Abioye, and A. U. Antia 384
Change of reference style 390

Short reports

Comparison of IV salbutamol with IV aminophylline in the treatment of severe, acute asthma in childhood. G. Hambleton and M. J. Stone 391
Adder bites in children. R. N. Wild 392
Coeliac disease in identical twins. F. J. Penna, J. A. C. Mota, M. L. V. Roquete, A. S. T. de Carvalho, A. T. de Oliveira Lemos, A. J. A. Barbosa, E. Leao, R. A. Ferreira, and L. de Paula Castro 395
Recurrent attack of rotavirus gastroenteritis after adenovirus-induced diarrhoea. S. Chiba, R. Kogasaka, M. Akihara, K. Horino, and T. Nakao 398
Pathogenesis of oxytocin-induced neonatal hyperbilirubinaemia. S. Singhi and M. Singh 400
Correspondence 403
Book reviews 408

No. 6 June 1979

Original articles

Clinical events relating to intraventricular haemorrhage in the newborn. M. Fujimura, D. M. Salisbury, R. O. Robinson, P. Howat, P. M. Emerson, J. W. Keeling, and J. P. M. Tizard 409
Effect of feeding on neonatal oxygen consumption. J. K. Stothers and R. M. Warner 415
Hearing loss in very low birthweight infants treated with neonatal intensive care S. J. Abramovich, S. Gregory, M. Slemick, and A. Stewart 421
1028 neonatal electrocardiograms. R. W. A. Jones, C. Sharp, L. R. Rabb, B. R. Lambert, and D. A. Chamberlain 427
Sinusoidal heart rate rhythms in severe neonatal hypoxia. M. McC. Reid, J. Jenkins, and G. McClure 432
Breath hydrogen test for detecting lactose malabsorption in infants and children: prevalence of lactose malabsorption in Japanese children and adults. O. Nose, Y. Iida, H. Kai, T. Harada, M. Ogawa, and H. Yabuuchi 436
Giant exomphalos—conservative or operative treatment? D. C. S. Gough and A. W. Auldist 441
Defective *Candida* killing in childhood malnutrition. R. Tuck, V. Burke, M. Gracey, A. Malajczuk, and Sunoto 445
Bronchial asthma in Nigerian children. W. I. Aderele 448
Carbamazepine dose-frequency requirement in children. G. W. Rylance, T. A. Moreland, and G. M. Butcher 454
Osteoid osteoma and benign osteoblastoma in childhood. J. A. Black, R. K. Levick, and W. J. W. Sharrard 459
Cushing's disease presenting with growth failure: clinical remission during cyproheptadine therapy. D. B. Grant and S. M. Atherden 466

Short reports

Rectal paracetamol in small children with fever. S. Vernon, C. Bacon, and D. Weightman 469
Acute infantile thrombocytosis and vitamin K deficiency associated with intracranial haemorrhage. J. Lorber, J. S. Lilleyman, and E. B. Peile 471
Premature menarche without other evidence of precocious puberty. M. E. Heller, J. Dewhurst, and D. B. Grant 472
A boy with low-TSH hypothyroidism. P. J. Smail, T. E. Isles, and R. S. Ackroyd 475
Ring 20 chromosome in a child with seizures, minor anomalies, and retardation. J. M. Stewart, N. Cavanagh, and D. T. Hughes 477
Scottish Paediatric Society 480
Change of reference style 481
Correspondence 482
Book reviews 487

No. 7 July 1979

James Spence Medallist, 1979 489

Original articles

Physiological responses of the newborn infant to resuscitation. A. W. Boon, A. D. Milner, and I. E. Hopkin 492
Metabolic and hormonal responses of low birthweight infants to intravenously infused calories not exceeding the maintenance energy expenditure. I. Rubecz, J. Mestyán, P. Varga, and Gy. Soltész 499
***Mycoplasma pneumoniae* infection: a follow-up study of 50 children with respiratory illness.** J. Y. Q. Mok, P. R. Waugh, and H. Simpson 506
Normal children with large heads—benign familial megalencephaly. R. E. Day and W. H. Schutt 512
Four families with immunodeficiency and chromosome abnormalities. D. C. A. Candy, A. R. Hayward, D. T. Hughes, L. Layward, and J. F. Soothill 518
Effects of physical training on hormonal responses to exercise in asthmatic children. S. Leisti, M-J. Finnilã, and E. Kiuru 524
Dubin-Johnson syndrome with some unusual features in a Chinese family. N. S. Lo, C. W. Chan, and J. H. Hutchison 529
Carrier detection in Duchenne muscular dystrophy: evidence from a study of obligatory carriers and mothers of isolated cases. J. R. Sibert, P. S. Harper, R. J. Thompson, and R. G. Newcombe 534
Cytomegalovirus and blood transfusion in neonates. J. W. T. Benson, S. J. Bodden, and J. O'H. Tobin 538
Comparative trial of manual and mechanical percussion technique with gravity-assisted bronchial drainage in patients with cystic fibrosis. M. Maxwell and A. Redmond 542
Serum C-reactive protein test in diagnosis of septic complications of cerebrospinal fluid shunts for hydrocephalus. R. Bayston 545
Change of reference style 548

Short reports

Two cases of perinatal listeriosis. M. H. Robertson, N. G. Mussalli, T. A. Aizad, J. M. Okaro, and G. S. Banwell 549
Water intoxication by the oral route in an infant. A. Etzioni, A. Benderley, and Y. Levi 551
Copper deficiency in a low birthweight infant. P. Yuen, H. J. Lin, and J. H. Hutchison 553

No. 7 July 1979—*continued*

Pulmonary candidiasis in cystic fibrosis. B. M. Jenner, L. I. Landau, and P. D. Phelan 555
Effective treatment for rhinopulmonary mucormycosis in a boy with leukaemia. O. B. Eden and J. Santos 557
Neonatal aspergillosis accompanying fulminant necrotising enterocolitis. H. H. Mangurten and B. Fernandez 559
Correspondence 563
Book reviews 568

No. 8 August 1979

Review article

Juvenile diabetes mellitus: possibility of prevention. J. W. Farquhar 569

Original articles

Status asthmaticus in children: a one-year study. S. A. McKenzie, A. T. Edmunds, and S. Godfrey 581
Role of viruses and bacteria in acute wheezy bronchitis in childhood: a study of sputum. M. E. C. Horn, S. E. Reed, and P. Taylor 587
Changing incidence of neonatal hypermethioninaemia: implications for the detection of homocystinuria. P. D. Whiteman, B. E. Clayton, R. S. Ersser, P. Lilly, and J. W. T. Seakins 593
Lymphocyte response after surgery in the neonate. P. Puri, D. J. Reen, O. Browne, P. Blake, and E. J. Guiney 599
Critical assessment of small bowel biopsy in children. J. F. T. Glasgow, C. W. B. Corkey, and A. Molla 604
Use of growth hormone-gel. B. Lippe, S. D. Frasier, and S. A. Kaplan 609
Pulmonary hypoplasia: lung weight and radial alveolar count as criteria of diagnosis. S. S. Askenazi and M. Perlman 614
Neutrophil function in children with acute lymphoblastic leukaemia in the presence and absence of viral infections. M. M. Reid, A. W. Craft, and W. T. Low 619
Intrathecal serotherapy in neonatal tetanus: a controlled trial. M. R. Sedaghatian 623

Current topics

A suggested child-health clinic form. R. S. Illingworth 626

Short reports

Neonatal small left colon syndrome. L. Rangecroft 635
Acute necrotising fasciitis due to streptococcal infection in a newborn infant. J. Nutman, E. Henig, E. Wilunsky, and S. H. Reisner 637

Reduced Subscription Rates for Junior Hospital Doctors Residents and Interns...

from January 1 1979

Archives of Disease in Childhood

will be available to junior doctors in all parts of the world for a maximum of four consecutive years at REDUCED Annual Subscription Rates. (Thereafter, or when reaching consultant status this special offer will no longer apply.) The following subscription rates apply for the twelve issues published in 1979.

Inland £17.00

Overseas US$40:00

(The full rates are: Inland £28.00; Overseas US$65.50)

The opportunity to subscribe to this journal of international authority and repute at a substantially reduced subscription rate is one not to be missed by junior doctors seeking to specialise in paediatrics.

Please complete the adjacent order form and send for your subscription NOW.

Further order forms can be supplied on request.

PEDIATRIC RESEARCH

Volume 12, No. 10 October 1978

Contents

The Relationship of Amniotic Membrane 11-Oxidoreductase Activity to Lung Maturation in the Human Fetus 957

A. K. Tanswell and B. T. Smith (Kingston, Ontario, Canada)

The findings demonstrate that in pregnancies where the fetus is destined to develop respiratory distress syndrome after delivery, the amniotic membranes are defective in their ability to produce cortisol, resulting in a possible reduction in the amount of cortisol available to the fetal lung during maturation *in utero*.

Cellular and Humoral Immunity in Cartilage-Hair Hypoplasia 961

M. Virolainen, E. Savilahti, I. Kaitila, and J. Perheentupa (Helsinki, Finland)

In an unselected series of 28 subjects with cartilage-hair-hypoplasia, almost all subjects had subnormal responses in tests of cellular immunity, although most of them had no apparent unusual susceptibility to infections. This feature was a more constant feature of the syndrome than the hair abnormality.

Salivary Amylase in Cystic Fibrosis: A Marker of Disordered Autonomic Function 967

G. P. Davidson, A. Koheil, and G. G. Forstner (Toronto, Ontario, Canada)

To determine whether an increased salivary isoenzyme activity might be present in cystic fibrosis, these scientists examined total serum amylase and isoenzyme patterns from a series of patients, including cystic fibrosis (CF) patients with and without steatorrhea, patients with exocrine pancreatic insufficiency without CF (Shwachman's syndrome), and a control group who had neither CF nor pancreatic insufficiency.

The Effect of Racemic, D-Propranolol, L-Propranolol, and Practolol on the Response to Cold by the Newborn Rabbit 971

I. Dober, V. Jaszai, T. Heim, and R. D. G. Milner (Pecs, Hungary, Toronto, Canada, and Sheffield, England)

In this investigation the newborn rabbit has been used as a model to investigate the effects of propranolol, the isomers of propranolol, and practolol on the response to cold exposure.

Fetomaternal Potassium Relations in the Rat on the Twentieth Day of Gestation. II. Effects of Maternal Hypocalemia 977

A. G. Fantel (Seattle, Washington)

A study of potassium homeostatis during maternal hyypokalemia was undertaken in potassium-deficient rats on the 20th day of gestation.

Plasma 25-Hydroxyvitamin D in Familial Hypercholesterolemic Children Receiving Colestipol Resin 980

R. C. Tsang, M. S. Roginsky, M. J. Mellies, and C. J. Glueck (Cincinnati, Ohio)

The effects of colestipol, a new synthetic organic bile sequestrant polymer (U26-597A), on vitamin D metabolism have been assessed in children with familial hypercholesterolemia over a 2-year period.

Pulmonary Diffusing Capacity in Lambs During the Early Neonatal Period 983

J. M. Bissonnette, W. H. Drummond, W. K. Wickham, and J. Z. Cronan (Portland, Oregon)

When a rebreathing method to measure pulmonary diffusing capacity in neonatal lambs was employed, a significant increase in diffusing capacity was found to take place in the first day of life.

Distortions in Fetal Growth Standards 987

R. L. Naeye and J. B. Dixon (Hershey, Pennsylvania)

The findings of the present studies indicate that widely used fetal growth standards appear to include measurements from both growth-retarded neonates and from neonates older than their calculated gestational ages.

Maturation of *p*-Aminohippuric Acid Transport in the Developing Rabbit Kidney: Interrelationships of the Individual Components 992

B. R. Cole, J. T. Brocklebank, R. G. Capps, B. N. Murray, and A. M. Robson (St. Louis, Missouri)

This investigation was undertaken to examine systematically the contribution of the individual cellular mechanisms to the reduction on aryl acid excretion in the immature rabbit kidney with *p*-aminohippuric acid being used as the test aryl acid.

Abnormal Colonization of Neonates in an Intensive Care Unit: Means of Identifying Neonates at Risk of Infection 998

K. Sprunt, G. Leidy, and W. Redman (New York, New York)

Results of these studies indicate that serial throat cultures permit selection of the group of Intensive Care Unit neonates at greatest risk of infection and indicate the probable organism from which they are at risk.

ALLERGY IN CHILDREN

Jan A Kuzemko

Allergic disorders in children cause a great deal of suffering. Some, such as asthma, are life-threatening. Yet until recently such disorders were greatly neglected. Now we have a greater knowledge of allergies.

This book is based on the author's experience in a special allergy clinic during the last ten years.

Will be of value to all those dealing with sick children, particularly paediatricians, GP's, allergists and even some parents.

CONTENTS: Incidence and Genetic Aspects of Allergic Disease. Causes of Allergy in Children. History, Examination and Investigation. Food Allergy. Skin Allergy. Allergic Disease of the Upper Respiratory Tract. Ears. Asthma. Eyes. Allergic Reaction to Insect Bites and Stings. Drug Allergy. Allergy and Cystic Fibrosis. Allergy and the Nervous System. Index.

128 pages Cased Illustrated £5.00 net

ASTHMA IN CHILDREN

Jan A Kuzemko

This short text by the same author is also based on his experience. All aspects of asthma are covered and the review of drugs used in treatment is completely up-to-date.

CONTENTS: Definition. Incidence, Prognosis and Mortality. Physiology and Pathology of the Lung. Immunology. Lung Function Tests and Their Interpretation. History-taking, Examination and Investigations. Emergency Treatment. Long-term Management. Recent Advances in Drug Therapy. Appendix: Some Useful Drugs in Asthma. Index.

128 pages Cased Illustrated £4.00 net

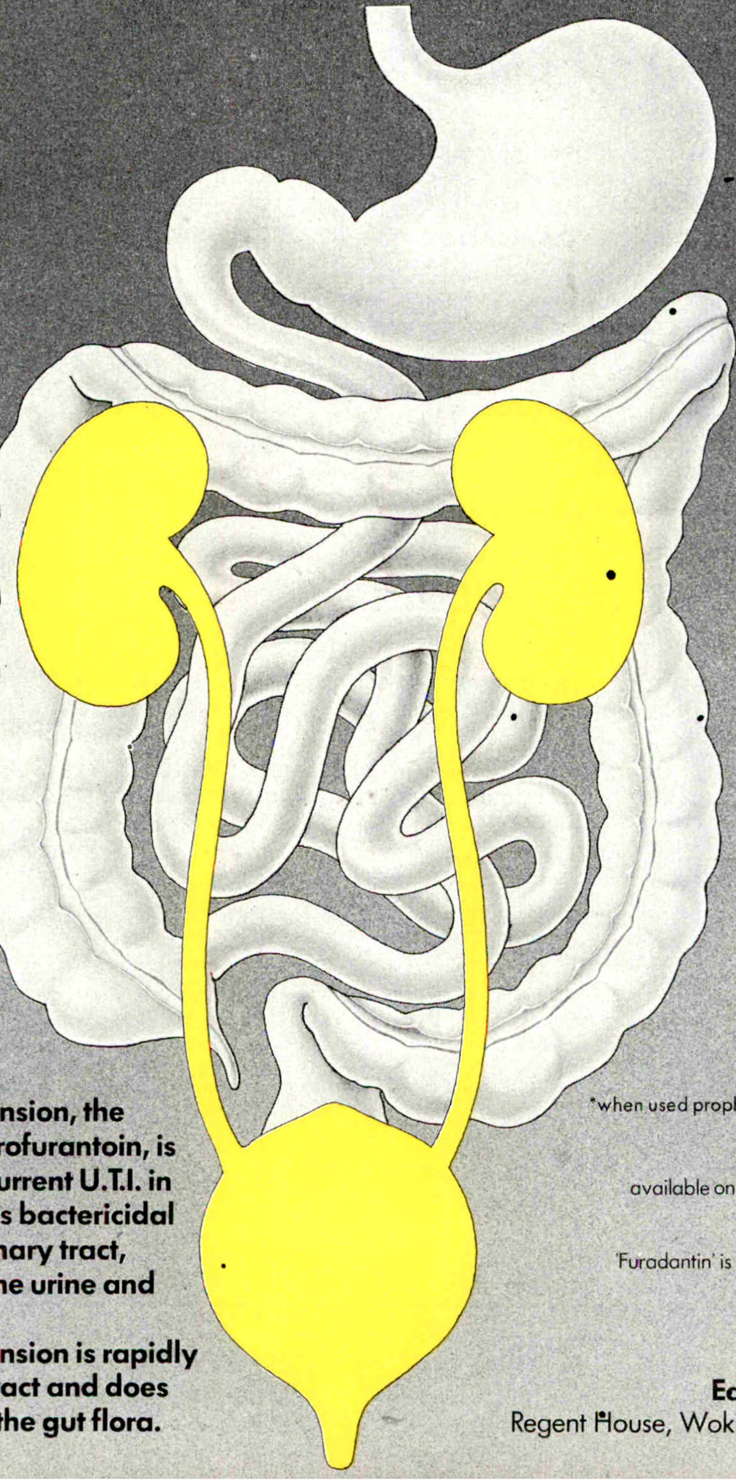
Furadantin Suspension

(nitrofurantoin)

To prevent lower urinary tract reinfection in childhood*



Furadantin Suspension, the only liquid form of nitrofurantoin, is recommended for recurrent U.T.I. in childhood because it is bactericidal and specific to the urinary tract, being active in both the urine and the renal medulla.

Furadantin Suspension is rapidly absorbed in the G.I. tract and does not cause changes in the gut flora.

*when used prophylactically in susceptible individuals

Further information is available on request to the company.

PL 0364/0010 PA 170/5/3

'Furadantin' is a registered trade mark.

Intellectual performance in children after circulatory arrest with profound hypothermia in infancy

D. F. DICKINSON AND J. E. SAMBROOKS

Royal Liverpool Children's Hospital

SUMMARY 38 children were assessed 22 months to 6 years after open heart surgery using circulatory arrest with deep hypothermia. The mean IQ of the group was 99·2 (SD 19·5). No correlation was found between IQ and the age or weight at operation or the duration of circulatory arrest. The results suggest that the technique gives effective protection to the brain during periods of circulatory arrest for up to 60 minutes.

Surgical treatment in early infancy is sometimes necessary in children with congenital heart disease either because of intractable cardiac failure or arterial hypoxia. The combined mortality from early palliation followed by later total correction led to attempts at complete correction as a primary procedure. However, early experience with standard cardiopulmonary bypass in infancy was associated with major problems in most centres (Baffes, 1968; Ching *et al.*, 1971; Hallman and Cooley, 1971) and although cardiopulmonary bypass has now successfully been used (Sugimura and Starr, 1977), many centres continue to use deep hypothermia with circulatory arrest for these patients. The technique offers the surgeon almost ideal operating conditions in an empty, still, and bloodless heart and several successful series of complete repairs of complex malformations have been reported (Mori *et al.*, 1972; Barratt-Boyes, 1973; Venugopal *et al.*, 1973).

The vulnerability of the developing brain to a number of insults has been well documented (Dobbing, 1974) and concern has existed regarding the long-term intellectual development of children subjected to periods of circulatory arrest in infancy. Although reports of neurological damage (Bjork and Hultquist, 1962) severely curtailed the use of deep hypothermia in the early 1960s, the incidence of serious neurological complications in the infants reported by Mori *et al.* (1972) was low, and subsequent reports have suggested that in the longer term, intellectual function remains within the normal range in most cases (Brunberg *et al.*, 1974; Stevenson *et al.*, 1974; Messmer *et al.*, 1976; Haka-Ikse *et al.*, 1978). Nevertheless, in each series abnormal neurological behaviour in the immediate postoperative period and later intellectual retardation was seen in a significant number of patients and further evaluation of the technique is needed.

Patients and methods

Between January 1971 and December 1975, 84 children underwent surgical correction of congenital heart disease at the Royal Liverpool Children's Hospital using deep hypothermia (core cooling) with circulatory arrest. During the period this technique was used, with few exceptions, for all children requiring open heart surgery at <2 years of age, or below 10 kg in weight. There were 29 deaths in hospital and one death later. One child has been lost to follow-up. Four children subsequently required a 2nd operation which was carried out under hypothermic conditions in 3 and using standard cardiopulmonary bypass in the 4th.

Assessment of intellectual ability was made by one of us (J.E.S.) in 38 of the 54 long-term survivors, 22 months to 6 years after operation. At the time of testing, the ages of the children ranged from 28 to 105 months (median 50). The children were those attending the hospital for a routine outpatient visit during 1976 and 1977 and those living in the immediate vicinity of Liverpool. No child was excluded because of a neurological abnormality noted before the operation. An informal interview with the parent(s) was followed by assessment of the child on one of four tests selected according to the age and ability of the child. The Wechsler preschool and primary scale of intelligence or the Wechsler

Cardiac Unit, Royal Liverpool Children's Hospital
D. F. DICKINSON, senior registrar
J. E. SAMBROOKS, senior clinical psychologist

intelligence scale for children was used in 14 children and the Merrill Palmer scale of mental tests in 23. One severely handicapped child was assessed using the Griffiths developmental scale. In addition, all the children were assessed on the Vineland scale of social maturity.

The cardiac lesions of the tested children are given in Table 1. At time of operation the median age of the children was 9 months (range 5 days to 36 months), the mean weight 6·5 kg (range 2·4 to 12·3), and the mean duration of circulatory arrest 47 min (range 20 to 69). Hypothermia from 14 to 25°C (nasopharyngeal) was used, most children being arrested at 18 or 19°C. In these respects there were no significant differences between the tested group, the group of survivors as a whole, or the 29 children who did not survive.

Surgical technique. The surgical technique was described in detail previously (Hamilton *et al.*, 1973).

After induction of anaesthesia, lines for the continuous monitoring of arterial and central venous pressure are established. The electrocardiograph, nasopharyngeal, and oesophageal temperatures are also monitored continuously during the procedure. Cardiopulmonary bypass is established using a single right atrial cannula with pump return to the ascending aorta. A period of perfusion at 2·4 l/m^2 with the Temptrol infant model oxygenator (Bentley Laboratories Inc., USA) in conjunction with an infant heat exchanger, is used to maintain the rate of cooling between 0·5 and 1·0°C/min. After reaching a predetermined low temperature (usually 18°C) perfusion is continued for a further 5 minutes to allow for temperature equilibration within the body. The infant is then exsanguinated through the venous line, snares are applied to the venae cavae, and a single clamp is applied to the aorta and pulmonary artery to lessen the risk of air embolism. After repair of the cardiac lesion is complete, perfusion is re-established and rewarming is begun. Acidosis is corrected at 32°C and inotropic drugs used if necessary to support the circulation.

Results

The mean IQ of the 38 tested children was 99·2 (SD 19·5). On the Vineland scale of social maturity the mean score was 112 (SD 19). There was no significant difference in mean IQ between those patients tested using the Merrill Palmer scale of mental tests, and those tested using either the Wechsler intelligence scale for children or the Wechsler preschool and primary scale of intelligence. Although the number of patients in some groups is small, no statistically significant correlation was found between IQ and age at operation (Fig. 1), weight at operation (Fig. 2), and duration of circulatory arrest (Fig. 3). Children with cyanotic congenital cardiac lesions (mean IQ 99) did not score significantly lower than those with acyanotic lesions (mean IQ 99·7), and there was no significant

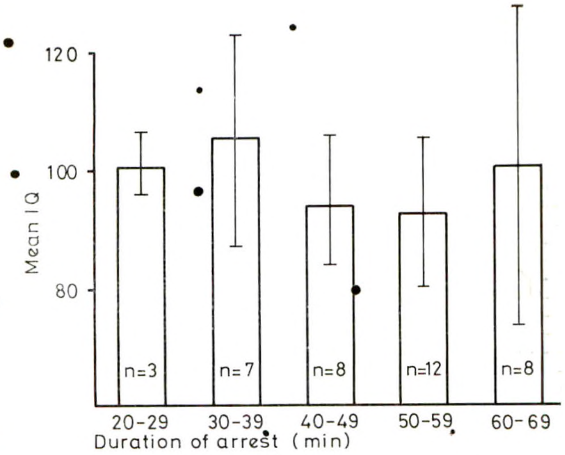
difference in mean IQ between the four main diagnostic categories (Fig. 4).

Seven (18%) children had IQ scores of at least 1 SD below the mean of the test (Table 2). Three were patients known to have neurological abnormalities dating from before the time of operation. Low cardiac output, with convulsions on the 4th post-operative day may have contributed to brain damage in one child, and one child (Case 6, Table 2) underwent 2 operations at an age at which we would now consider this technique to be inappropriate. A 6th child was uncooperative during testing. She attends a normal primary school and may well come within the normal range on retesting. No satisfactory explanation for retardation was found in the 7th child. One other child developed abnormal neurological signs in the postoperative period, but now has an IQ of 86 and a social quotient of 105 and attends a normal school.



Brackets indicate ± 1 SD.

Brackets indicate ± 1 SD.

TGV	Transposition of great vessels
VSD	Ventricular septal defect
TAPVC	Total anomalous pulmonary venous connection
FT	Fallot's tetralogy

Fig. 4 *IQ in relation to type of cardiac defect*

Most children assessed using Wechsler tests showed good correlation between verbal and performance scores. In 3 children however, an abnormal discrepancy was present, the performance score being significantly higher in 2 and the verbal score higher in the 3rd.

Discussion

The results of experiments in laboratory animals have shown that oxygen consumption and cerebral

TGV = transposition of great vessels; VSD = ventricular septal defect; TAPVD = total anomalous pulmonary venous drainage; APW = aortico pulmonary window.

metabolic rate decrease at between 6 and 15%/°C fall in brain temperature (Rosomoff and Holladay, 1954; Hägerdal *et al.*, 1975). Within the range of hypothermia usually used in cardiac surgery at present, the relationship between cerebral oxygen consumption and temperature is probably linear. With this information, the safe period of circulatory arrest at between 16 and 19°C has been extended to between 60 and 75 min (Barratt-Boyes, 1973) and arrest periods of up to 120 min at 10°C have been reported (Belsey *et al.*, 1968). The possibility of neurological damage or intellectual impairment resulting from prolonged circulatory arrest or deep hypothermia has been appreciated for many years. Bjork and Hultquist (1962) reported 5 cases of fatal brain damage in children after hypothermic circulatory arrest. Histologic study of the brains in these patients showed a reduction in the number of ganglion cells in the globus pallidum with similar changes in the parietal cortex, hippocampus, and thalamus. Refinements in technique led by the University of Washington (Mohri *et al.*, 1969) and the University of Kyoto (Hikasa *et al.*, 1967) have enabled surgeons to operate safely in small infants with few major neurological complications.

Most centres have favoured the use of surface cooling to induce hypothermia, but metabolic studies of both surface-cooled and core-cooled patients have failed to establish conclusively the superiority of either technique (Harris, 1973). The advantages of core rewarming are widely accepted (Mori *et al.*, 1972; Barratt-Boyes *et al.*, 1973). Since 1970 we have used a technique of core cooling and core rewarming with a low incidence of cerebral problems. Although the mortality in the earliest years of the period was high, during 1973–77 the mortality rate was 22% in 102 patients under one year of age (Di Eusanio *et al.*, 1979).

Our results show no significant difference between the mean IQ of the survivors of hypothermic circulatory arrest and the mean of the normal population. The results compare favourably with the mean IQ previously reported in children with congenital heart disease who had not undergone corrective surgery (Linde *et al.*, 1967; Silbert *et al.*, 1969). Similar results have also been reported in a group of children who underwent corrective surgery at <2 years using conventional cardiopulmonary bypass (Sunderland *et al.*, 1973). Although these results are encouraging, in our series the range of intelligence within the tested group shows a wider dispersion about the mean than would be expected in a normal population, and a significant proportion of the survivors showed evidence of intellectual retardation. However, in 3 children, there was clear evidence before operation of neurological dysfunction of sufficient severity to explain their present disability (Table 2). If these patients are excluded the mean IQ of the group is 102 (SD + 17) and does not differ significantly from the distribution of intelligence within the normal population.

Laboratory studies of many animal species have shown that the immature animal is more tolerant of the effects of acute hypoxia than the adult (Dawes, 1968). In man, brain growth is known to continue to age 18 months (Dobbing, 1974) and the neonate might therefore be expected to show greater tolerance to a given period of circulatory arrest than the more mature child. The possibility that increasing age at the time of operation might be associated with a lower rate IQ score was suggested by Messmer *et al.* (1976). Our results show a similar tendency but the number of children >age 18 months at the time of operation is small and the correlation is not statistically significant. Nevertheless, the occurrence of mental retardation in 2 of the 4 patients who underwent operation at >2 years of age suggests that particular caution is needed if the technique is to be used at this age. Our current policy (Di Eusanio *et al.*, 1979) is to use this technique only in a few selected cases at age >12 months.

Neurological sequelae after circulatory arrest with hypothermia include convulsions, paresis, hypotonia, rigidity, choreoathetosis, alteration of consciousness or personality, and impairment of intellect (Björk and Hultquist, 1962; Mohri *et al.*, 1969; Mori *et al.*, 1972; Venugopal *et al.*, 1973; Brunberg *et al.*, 1974). Similar complications have been described after operation using conventional cardiopulmonary bypass (Gilman, 1965; Javid *et al.*, 1969). Many factors may be responsible for such neurological damage. Cardiopulmonary bypass, used both for cooling and rewarming may be complicated by embolisation of gas, fat, or fibrin-platelet aggregates (Aguilar *et al.*, 1971). Regional impairment of cerebral microvascular perfusion has been shown in experimental animals during core cooling and rewarming, and may be a factor in creating uneven cerebral cooling (Aoyagi *et al.*, 1975). Rapid core cooling may allow excessive temperature gradients to develop between blood and cerebral tissue and we take considerable care to control the rate of cooling (Di Eusanio *et al.*, 1979). Since cerebral blood flow is influenced by changes in arterial P_{CO_2} (Lassen, 1974), carbon dioxide concentrations of 10% are used in the inspired gas mixture below 30°C to promote cerebral vasodilatation during cooling. Accumulation of cerebral metabolites during prolonged circulatory arrest could also be a factor in the production of postoperative cerebral damage. However, if this were the case, it might be expected that longer periods of arrest would be associated with poorer intellectual function in the survivors. Our results do not support this conclusion, and suggest that the technique gives effective protection to the brain for periods of up to 60 min of circulatory arrest, and possibly for up to 70 min.

Previous authors (Linde *et al.*, 1967; Silbert *et al.*, 1969) have noted the tendency for older children with cyanotic congenital heart disease to have significantly lower IQ scores than children with acyanotic congenital heart disease. From their results, Silbert *et al.* (1969) came to the tentative conclusion that chronic hypoxia in the first 2 years of life might, by itself, have direct adverse effects on sensorimotor development, irrespective of any effect resulting from the reduced exercise tolerance of the cyanotic child. Linde *et al.* (1967), on the other hand, suggested that physical incapacity in the young child with cyanosis was the most important factor in the observed lower scores, and that this deficit in gross motor performance might result in an underestimation of the potential intellectual performance at a later age. In the present series defects were corrected, in all but 4 cases, before age 2 years and no significant difference in IQ was seen between the two groups. The possibility of psychological benefit resulting from early correction, although unlikely ever to be a major consideration in the timing of surgery, should not be discounted.

Detailed developmental assessment was not performed before operation and, indeed, many of the patients were sufficiently ill at that time for such testing to be of doubtful predictive value. We were unable therefore to use the patients as their own controls. Nevertheless, the distribution of intelligence within the tested group closely resembles that of the normal population, and suggests that the technique is effective in protecting the brain during prolonged periods of circulatory arrest.

We thank Mrs C. Smallman for technical assistance, Miss S. J. McIlrath for secretarial help, and Professor F. Harris for his help and advice.

This study was supported by a grant from the Mersey Regional Health Authority.

Congenital complete heart block in the newborn associated with maternal systemic lupus erythematosus and other connective tissue disorders

J. D. HARDY, S. SOLOMON, G. S. BANWELL, R. BEACH, V. WRIGHT, AND F. M. HOWARD

Princess Alexandra Hospital, Harlow

SUMMARY Four babies with complete heart block associated with maternal systemic lupus erythematosus (SLE) are described, together with a 5th baby whose mother had serological abnormalities only. One baby had a rapidly fatal outcome, one has required digoxin for heart failure, and the remaining 3 are asymptomatic but remain in complete heart block. Additional manifestations were present in 2 of them. The spectrum of neonatal abnormalities that may occur in association with maternal SLE and related connective tissue disorders is discussed, together with the possible causes and the prognosis. We conclude that congenital heart block is more common than had previously been appreciated.

Congenital complete heart block, sometimes presenting with bradycardia before birth (Sankey, 1948), is a rare clinical entity present in about one in 20 000 live births (Michaelsson and Engle, 1972). Familial occurrence has been reported a number of times since the first description by Morquio (1901).

In about 30% of cases there is another congenital abnormality (Michaelsson and Engle, 1972) the most common of which is corrected transposition of the great arteries (Walker *et al.*, 1958), but an association with other congenital anomalies has been reported (Nadas and Fyler, 1972).

Of those cases with no associated abnormality some probably result from abnormal development of the embryonic conducting system (Lev, 1972). It is possible that others result from disruption of the conducting system by some inflammatory process *in utero* (Carter *et al.*, 1974), and there have been reports of an association between congenital complete heart block in the newborn and SLE in the mother. We can find only one report in the UK (Hull *et al.*, 1966), but we believe it is more common here than generally appreciated and we wish to report a further 5 cases, with survival in 4, to show that this is part of a spectrum of abnormalities which may be associated with maternal connective tissue disease.

Patients

Case 1. A boy born by vertex delivery at 31 weeks' gestation weighing 1·9 kg (1972). He was grossly hydropic with respiratory distress and cyanosis. The heart rate was extremely slow at 50/min. There was hepatosplenomegaly. The ECG showed complete heart block with an atrial rate of 150/min and a ventricular rate of 54/min. Despite supportive therapy he died at 36 hours. Unfortunately no detailed postmortem examination was performed.

Maternal history

The child's mother, born 1942, became extremely ill at age 21 with pericarditis, pleurisy, anaemia, arthralgia in the small joints of the hands, and episodes of paroxysmal tachycardia. Investigations at that time included a differential agglutination titre (DAT) for rheumatoid factor, positive at over 2560.

After delivery of the baby, the advice of one of us (V.W.) was sought and further investigation led to the maternal condition being diagnosed as SLE.

Princess Alexandra Hospital, Harlow, Essex
Department of Paediatrics
J. D. HARDY, consultant paediatrician
S. SOLOMON, paediatric senior house officer
Department of Obstetrics and Gynaecology
G. S. BANWELL consultant obstetrician and gynaecologist
Brompton Hospital, London
R. BEACH, senior house officer
Rheumatism Research Unit, School of Medicine, Leeds
V. WRIGHT, professor of rheumatology
Royal Free Hospital, London
F. M. HOWARD, paediatric senior registrar

The laboratory findings included an ESR of 120 mm in the 1st hour; gross hypergammaglobulinaemia (6·6 g/100 ml); antinuclear factor (ANF) positive at 1:50 titre, and the DAT and latex fixation tests strongly positive, but an LE cell test was negative.

***Case 2.** A girl, born by assisted breech delivery at 40½ weeks' gestation weighing 2·73 kg (9.11.76). Bradycardia, which had been present from 2 months before delivery, persisted at birth, heart rate 72/min. There was no cyanosis, oedema, cardiomegaly, or murmurs. The liver was palpable 3 cm and spleen 2 cm below the costal margin. There were many circular, pale, somewhat atrophic, depressed lesions of about 1 cm diameter, some surrounded by an erythematosus circle predominantly on the face lateral and superior to the eyes (Figure), but also some lesions on the scalp, neck, and chest.

The skin lesions faded at age 2 weeks but subsequently became more florid and extensive, extending down the trunk and abdomen with one lesion on the thigh. The lesions tended to diminish and extend, but at age 3 months all that remained were a few small scarred slightly telangiectatic lesions that were hardly noticeable with some petechiae predominantly on the face. The spleen was impalpable after age 8 months. Her weight is now on the 3rd centile, but she appears to be well and is developmentally normal. She remains in complete heart block.

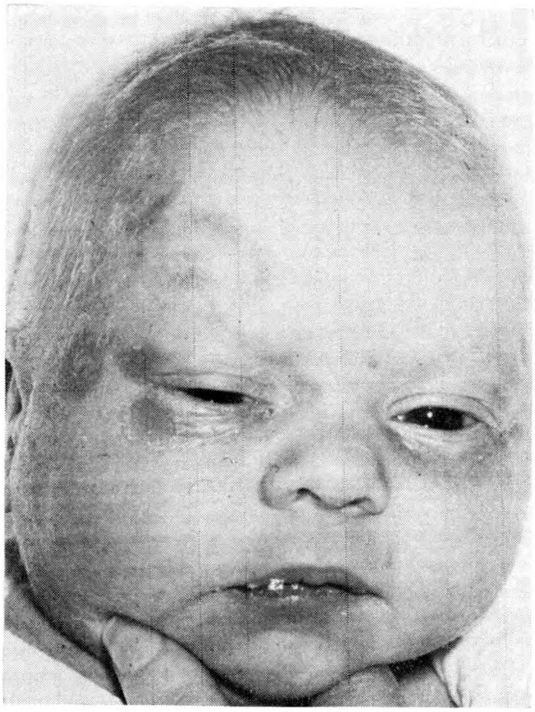

Figure *Case 2. Aged 3 days.*

Maternal history
The child's mother has suffered from SLE for 8 years manifested by lesions on the fingers and toes in the winter and discoid lesions on the face and chest in the summer. There has been no renal involvement and her general health has been good. Systemic corticosteroids or immunosuppressants have not been prescribed.

Previous pregnancies. Termination of pregnancy on social and medical grounds in 1972. Healthy baby boy weighing 2·875 kg born 1975 at 39½ weeks' gestation.

Investigations and diagnosis
The maternal diagnosis of SLE was made on the clinical and laboratory findings. Laboratory findings included a positive ANF with a speckled pattern of fluorescence on several occasions to a titre of 1 in 80; LE cells on 3 occasions: anti-DNA antibodies up to 103 units/ml (upper limit of normal 20); elutable nuclear antigen (ENA) positive at 1 in 64; Rose Waaler (RW) titre 1 in 80; total WBC frequently below 4×10^9/l (4000/mm^3). A skin biopsy from the foot showed a pronounced perivascular lymphocytic infiltrate with swelling of capillary endothelial cells.

No laboratory evidence for SLE was found in the baby apart from a weakly positive antinuclear antibody (ANA) test at 2 months. During the neonatal period simultaneous investigation of the baby and her mother included: full blood count, DNA binding, LE cells, RW test, immunoglobulins, and C3 and C4 component of complement. None was significantly abnormal in either. Neutropenia was found on one occasion at age 3 months in the baby (neutrophil count $0·95 \times 10^9$/l; 0·095/mm^3). ENA 3 months after delivery was positive in a titre of 1:64 in the mother but negative in the baby.

ECGs show complete heart block with an atrial rate of 130/min and a ventricular rate of 70 to 80/min. Chest *x*-rays showed a normal sized heart and normal pulmonary vasculature.

Case 3. A boy, born by caesarean section at term weighing 3·45 kg (10.1.77). Bradycardia, discovered shortly before delivery, persisted at birth with a heart rate of 60/min. His pulses were of good volume. There was a short grade 1 ejection systolic murmur audible in the pulmonary area and down the left sternal edge. There was no cyanosis and no oedema. Otherwise examination was negative and his general condition was good.

---

*This case was reported in *Clinical and Experimental Dermatology* (Rendall and Wilkinson, 1978) with emphasis on the dermatological aspects.

An ECG showed a rate of 60/min with complete heart block. The chest *x*-ray showed slight cardiac enlargement with normal lung fields. At 4 months when his heart rate was 58/min he was in mild heart failure and put on digoxin. He has remained well since.

Maternal history

The child's mother since age 24 has suffered from joint pains and stiffness, dryness and grittiness of the eyes, chilblains, and white hands in the cold. Her symptoms are ameliorated with prednisolone. The diagnosis of SLE and Sjogren's syndrome were made on the history together with a positive latex fixation, RW test, and ANF positive to a titre of 1:500 with a homogenous pattern and a DNA binding of 75% (control 21%).

Previous pregnancies. Therapeutic abortion aged 21 years.

Case 4. A girl, weight 2·23 kg, was delivered normally at 38 weeks to a 34-year-old Jamaican in whom pregnancy had been complicated by persistent anaemia and an antepartum haemorrhage. The fetal heart was irregular during the last trimester. The child was noted to have a pulse rate of 60/min at birth. On examination she appeared to be otherwise normal and healthy although there was a short systolic murmur audible at the apex, and signs of very mild cardiac failure. An ECG confirmed congenital complete heart block, with a ventricular rate of 40/min, an atrial rate of 150/min, and narrow QRS complexes. There were also several brief episodes of ventricular tachycardia during the first 24 hours of life. The chest *x*-ray showed cardiomegaly. An echocardiogram was normal, as was the arterial oxygen tension in 100% inspired oxygen.

It transpired that the mother had suffered for a number of years with joint pains, rashes, and anaemia. Her ANF was positive in 1974 and again after the birth of the baby. The child's ANF was positive on day 3 but no skin lesions or haematological abnormalities were found. The cardiac failure settled rapidly without specific treatment. At 7 days the child was well and thriving although the systolic murmur and cardiomegaly remained. At 3 months the child remains well and there would appear to be no associated anomaly.

Case 5. A girl, born by vertex delivery at term weighing 2·48 kg (9.3.77). Fetal bradycardia was noted at 38 weeks' gestation, and at birth the heart rate varied between 56 and 60/min. On examination she appeared otherwise healthy and normal. An ECG showed complete heart block with an atrial rate of about 160/min, and a ventricular rate of 56 to 60/min. The chest *x*-ray was normal. She is asymptomatic and growing normally.

Maternal history

The child's mother, aged 35, has no symptoms suggestive of a connective tissue disorder, but has a weakly positive ANF of 1:10 and a positive rheumatoid factor of 1:64.

Previous pregnancies. A girl, born in 1971, completely normal and healthy.

Clinical and laboratory findings

The clinical and laboratory findings in Cases 1–5 are shown in the Table. The maternal diagnosis of SLE is indisputable in Cases 2 and 3 with the history plus the serological finding of raised DNA binding, and it is probable in Cases 1 and 4. Case 3 suffers also from Sjogren's syndrome. In Case 5 there are serological abnormalities only.

The 4 symptomatic mothers have all had symptoms for some years. There was an exacerbation of symptoms during pregnancy in the mother of Case 2. She had discoid skin lesions and so did her baby. On the whole the illnesses have been chronic and relatively mild with an absence of renal problems. Only in the mother of Case 3 were corticosteroids prescribed in the pregnancy. The mothers of Cases 1, 2, and 5 all had one normal baby each; the mothers of Cases 2 and 3 have each had one termination of pregnancy.

Four of the infants (Cases 2, 3, 4, and 5) are alive and well, although Case 3 required digoxin. Case 2 had discoid skin lesions and hepatosplenomegaly in addition to complete heart block. Case 1, who was hydropic at birth, also had hepatosplenomegaly. He was the only baby who died—on the 2nd day. Three of the 5 babies are small-for-dates (Cases 2, 4, and 5). Three are girls and 2 are boys.

Of the laboratory findings ANF is the only result to have been positive in all 5 mothers. It was also positive in the 2 babies (Cases 2 and 4) in whom it was tested.

Discussion

We have been able to find reports of 26 infants (of 20 mothers) with complete heart block associated with

Table *Clinical and laboratory findings in babies with complete heart block (Cases 1–5) and in their mothers*

Cases	*Sex*	*Weight (g)*	*Gestation (weeks)*	*Clinical condition of baby*	*Laboratory support for SLE in the baby*	*Maternal disease*	*Maternal support for SLE or other connective tissue disease*
1	M	1·97	31	1st pregnancy. Hydropic. Ventricular rate 54/min. Hepatosplenomegaly. Died 36 hours	No detailed necropsy. No investigations for SLE	SLE. Developed pericarditis, pleurisy, anaemia, fever, arthralgia 8 years before	ANF positive. DAT strongly positive
2	F	2·73	40½	3rd pregnancy. Ventricular rate 70/min. Discoid skin lesions Hepatosplenomegaly. Alive and well	Weakly positive ANA	SLE. 8-year history of discoid skin lesions, photosensitivity, chilblain-like lesions on hands and feet	ANA positive. LE cells. Raised DNA binding
3	M	3·45	40	2nd pregnancy. Ventricular rate 60–70/min. Heart failure at 4 months—digoxin started		SLE and Sjogren's syndrome. Pyrexia. Arthralgia, chilblains 4 years before	Latex fixation, RW, and ANF tests positive. Greatly raised DNA binding
4	F	2·23	38	Ventricular rate 40/min. Brief episodes of ventricular tachycardia. Alive and well	Positive ANF	Joint pains, rashes, and anaemia for several years	ANF positive
5	F	2·48	40	2nd pregnancy. Ventricular rate 56–60/min. Alive and well		Asymptomatic	ANF weakly positive. RW positive

maternal connective tissue disease in addition to our 5 cases: Plant and Steven, 1945; Hogg, 1957 (1 case); Wright *et al.*, 1959 (3 siblings); Hull *et al.*, 1966 (1 case); Altenburger *et al.*, 1977 (1 case); Chameides *et al.*, 1977 (6 cases); and McCue *et al.*, 1977 (14 cases).

Five of the 20 mothers were asymptomatic and had serological abnormalities only. 13 of the remaining 15 mothers were diagnosed as suffering from SLE, one from rheumatoid arthritis (RA) (McCue *et al.*, 1977), and one from the syndrome of hypocomplementaemia with cutaneous vasculitis (Chameides *et al.*, 1977). Many had suffered from their illnesses for some years, and had had an exacerbation during pregnancy. There had been renal involvement in some mothers and 4 were reported to have died soon after pregnancy.

One mother had twins (McCue *et al.*, 1977), 3 mothers had 2 siblings (Chameides *et al.*, 1977; McCue *et al.*, 1977), and one mother had 3 siblings—all with complete heart blocks (Wright *et al.*, 1959). Many of the mothers had normal siblings, but there appears to have been a high abortion rate in the families. The 11 mothers described by McCue *et al.* (1977) had 14 infants with complete heart block, 14 normal infants, and 5 abortions between them. The mother described by Hull *et al.* (1966) had 2 normal children, followed by one with discoid skin lesions, and then one with complete heart block and hepatosplenomegaly who died.

In fact 8 out of the 26 infants have died, 4 in the early neonatal period, and 4 later in childhood. None of our 5 infants with complete heart block had any associated cardiac abnormality, but 6 of the reported cases had at least one. Patent ductus arteriosus was present in 3 cases and transposition of the great vessels in 2. Two of the reported cases had, in addition to the complete heart block, discoid skin lesions and hepatosplenomegaly. Most of the surviving infants enjoy good health. The oldest patient is 24 and has given birth to 2 healthy children (McCue *et al.*, 1977). The sex ratio of the 26 cases is 16 female to 10 male. The results of serological tests have been reported on very few of these infants. McCue *et al.* (1977) reported one infant with high titres of ANA and Chameides *et al.* (1977) reported an infant with a negative ANA test.

In the whole series (including our cases) 22 (71%) out of 31 have so far survived.

Spectrum of neonatal disease

In a review of congenital SLE, Vonderheid *et al.* (1976) did not accept that complete heart block was a manifestation. However, it appears to be relatively common. The 31 cases known to us are unlike the 19 cases of other neonatal diseases (McCuistion and Schoch, 1954; Dias *et al.*, 1958; Nathan and Snapper, 1958; Seip, 1960; Epstein and Litt, 1961; Johnson, 1963 (cited by Reed *et al.*, 1967); Jackson, 1964; Hull *et al.*, 1966; Reed *et al.*, 1967 (2 cases); Cruveiller *et al.*, 1970; Jones, 1971; Hontani *et al.*, 1971; Goldberg and Diamond, 1973; Weiner, 1973 (2 cases cited by Goldberg and Diamond, 1973; Vonderheid *et al.*, 1976); Soltani *et al.*, 1974; Vonderheid *et al.*, 1976 (2 cases)), and unlike the 4 cases in which the neonatal illness was diagnosed as SLE but in which there was no maternal illness suggestive of SLE, with abnormal serological tests in 2 (Nice, 1962; East and Lumpkin, 1969; Vonderheid *et al.*, 1976 (2 cases)).

We have arbitrarily classified the cases of neonatal SLE into 4 groups.

I Babies with complete heart block with or without other manifestations (31 cases; as described above).
II Babies in whom the only clinical manifestation is discoid skin lesions (13 cases).
III Babies with manifestations other than or in addition to discoid skin lesions—mainly haematological (6 cases).
IV Babies with presumed neonatal SLE in the absence of maternal clinical disease (4 cases).

The various manifestations that have been reported may occur singly or in combinations, and in families siblings may be normal or have the same or different manifestations as the index cases. For example, Reed *et al.* (1967) described a first-born baby with discoid skin lesions who has a 4th born sibling with discoid skin lesions and splenomegaly.

Overall discoid skin lesions were present in 22 (41%) out of 54 cases. Three (16%) cases (including our Case 2) had the combination of complete heart block, hepatosplenomegaly, and discoid skin lesions. Splenomegaly with or without hepatomegaly was present in 12 (22%) infants. Haematological abnormalities—anaemia, and or leucopenia, and or thrombocytopenia—occurred in 8 (15%) cases. The only other clinical manifestations that have been described are inflammatory lesions of the hands (Dias *et al.*, 1958) and valvular heart disease (East and Lumpkin, 1969). Most of the noncardiac lesions were transient, diminishing or disappearing in the early months of life.

Sex incidence. Altogether there are 19 males and 34 females, and one other the sex of which is unknown to us. Where weights and gestation are known 15 (60%) out of 26 are light-for-dates. The maternal connective tissue disorder has been SLE in most cases. As with the families of infants with complete heart block, some pregnancies have resulted in abortions, some in the birth of normal babies, and some in the birth of babies with the same or other manifestations of congenital SLE. In many families there are relatives with connective tissue disorders.

The most common positive laboratory findings in the mothers and babies have been the ANF, the LE cell test, and rheumatoid factors, but no consistent correlation has been found between the presence or absence of these and the clinical condition of the baby.

The pathogenesis of complete heart block and the other abnormalities described in some infants of mothers with SLE or related connective tissue disorders is unknown. There is certainly evidence of an increased familial incidence of SLE and of some of the serological abnormalities which may be associated with it. Apart from the studies already quoted (Reed *et al.*, 1967; McCue *et al.*, 1977), Larsson and Leonhardt (1959) found 4 instances of familial SLE and more than 40 of familial chronic discoid LE.

SLE has been described throughout childhood. Peterson *et al.* (1963) described skin lesions of SLE in a child as young as 18 months, and Fish *et al.* (1977) included a child of 2. It is therefore not unreasonable to conclude that in some instances SLE might occur *de novo* in the newborn and not as a direct result of the maternal illness. The case described by East and Lumpkin (1969) may be an example of this.

The transplacental passage of some maternal factors, probably IgG antibodies, is the most likely mechanism for most cases. The transient nature of some of the manifestations, such as discoid skin lesions, would strongly support this.

Beck *et al.* (1966) were able to show that ANA can cross the placenta and that it has a half-life of about 16 days in the infant. They also showed that ANA can be present in the infant in the absence of disease, and it is known that some babies suffer from disease with no ANA detected, e.g. the case of Hontani *et al.* (1971). It therefore seems unlikely that transplacental passage of ANA is the cause of transient neonatal SLE although some other undetected antibody may be responsible. The LE cell factor is not constantly present in mother and infant pairs. It can be present in the infant with no pathological effects (Bridge and Foley, 1954). Neither DNA nor RNA antibodies were found in our Case 2 nor were they found in the mother after delivery. However, platelet antibodies were shown in a mother and baby both with thrombocytopenia (Nathan and Snapper, 1958).

Presumably various antibodies are concerned in different manifestations of the neonatal disease, but we have been unable to detect what these are. None of the serological markers of connective tissue diseases has been shown actually to cause the neonatal disease. Widespread endocardial fibroelastosis has been the histological change seen in the babies who have come to necropsy (Hogg, 1957; Hull *et al.*, 1966; Chameides *et al.*, 1977). In a review of pathological studies of hearts with congenital complete heart block by serial sectioning, Carter *et al.* (1974) drew attention to a group of hearts where the atrioventricular conducting system was disrupted by a process of connective tissue degeneration. These changes were similar to those found by Hogg (1957) and Hull *et al.* (1966) in the children of mothers with SLE. It is therefore suggested that maternal autoantibodies may cross the placenta and cause degeneration of the fetal conducting system. This may happen in more than one pregnancy (Wright *et al.*, 1959). Further support for an antibody derived from the mother being involved in the pathogenesis of complete heart block in the baby comes from the known occasional occurrence of complete heart block in adults with SLE (Becker, 1965; Moffitt, 1965). Necropsies from several cases have shown damage and replacement of conductive tissue by connective tissue, similar to that seen in cases of congenital complete heart block. Similar changes have been described in adults with rheumatoid arthritis (Lev, 1972).

It is not surprising that there is more than one maternal connective tissue disorder associated with these neonatal syndromes as there is considerable serological and, to a lesser extent, clinical overlap. The asymptomatic mothers presumably carry the same antibodies noxious to the fetus as the symptomatic mothers (e.g. our Case 5).

The relatively mild clinical course and prolonged duration probably reflects the fact that the women least seriously afflicted by their connective tissue disorders will have the most babies. In our 5 cases there was no history of spontaneous abortion in other pregnancies although in the families described by McCue *et al.* (1977) there was an abortion rate of about 30% which is in agreement with other authors (McGee and Makowski, 1970). We note a high (60%) incidence of light-for-dates infants. However, in spite of this and the congenital abnormalities that may occur in some babies the prognosis for most liveborn infants is good.

The most serious manifestation is complete heart block. 22 (71%) out of 31 have survived. The management and prognosis of these children would not seem to differ very much from that of congenital complete heart block of any other cause. If the ventricular rate is more than 40 and the atrial rate is less than 140 and the QRS complex is narrow, the prognosis may be as good as 90% survival, half of the deaths occurring in the first year of life (Michaelsson and Engle, 1972).

Some mothers had some exacerbation of their symptoms during pregnancy—the skin lesions in the mother of our Case 2 were particularly severe during 2 pregnancies—and in a few the SLE only became apparent during pregnancy or in the postpartum period. Most authors who have studied SLE in pregnancy comment on the tendency to exacerbation of symptoms at this time (Dubois, 1966; McGee and Makowski, 1970). However, in spite of exacerbation of symptoms during pregnancy some of these mothers have had further pregnancies.

Conclusions

Congenital complete heart block is the most serious of a number of abnormalities that may be present in liveborn babies of mothers with connective tissue disorders. This possibility should be considered in the differential diagnosis of fetal bradycardia. When a baby is born with complete heart block, assessment of the mother may sometimes show a hitherto unsuspected connective tissue disorder. The association of heart block in the baby and connective tissue disorder in the mother is probably more common than had generally been appreciated.

Heart block is but one of a number of manifestations that may be present, and it appears that an intriguingly wide spectrum of disorders can occur in both the mother and her infant. A possible way of investigating this phenomenon would be to find what immunological differences there are in successive pregnancies of women who produce infants with different manifestations of congenital SLE.

We thank Professor J. S. Scott, professor of obstetrics, and Dr Olive Scott, consultant paediatrician, Leeds, for their help with Case 1; Dr J. R. S. Rendall, senior registrar, Department of Dermatology, University College Hospital, and Mr Brian Newlands, chief scientific officer, Department of Pathology, Princess Alexandra Hospital, Harlow, for their help with Case 2; and Dr Pamela Davies, consultant paediatrician, the Hammersmith Hospital for some of the references. ENA estimations were carried out by Professor G. R. V. Hughes, Hammersmith Hospital.

Tables of clinical and laboratory details of the other infants with congenital SLE can be obtained from the authors on request.

Behavioural deviance in children with early treated phenylketonuria

J. E. STEVENSON, JANET HAWCROFT, MARY LOBASCHER, ISABEL SMITH,
O. H. WOLFF, AND P. J. GRAHAM

Departments of Child Psychiatry and Child Health, Institute of Child Health, London

SUMMARY A sample of 99 early treated phenylketonuric children showed higher levels of behavioural deviance than 197 matched controls. For boys this excess of behavioural deviance persisted when IQ was taken into account. For phenylketonuric girls however it was restricted to those with IQs<70. The type of behavioural deviance shown by the boys over the whole IQ range was predominantly neurotic. The levels of behavioural deviance found in phenylketonuric children were among the highest that have been reported for children with various handicapping conditions.

It has now been shown that early treatment of phenylketonuria (PKU) results in a reasonably full preservation of intellectual functioning, although there may be a failure to reach full cognitive potential (Berman and Ford, 1970; Hudson *et al.*, 1970; Koch *et al.*, 1973; Smith and Wolff, 1974). The behaviour and emotional development of early treated children has been less thoroughly investigated (Wood *et al.*, 1967; Hackney *et al.*, 1968; Siegel *et al.*, 1968; Frankenburg *et al.*, 1973). These aspects of personality development are of importance in children with PKU because of the inevitable stresses that they are likely to meet as a result of their highly artificial diet. The capacity to cope with this diet will depend on the child's own adjustment to an increasing extent as he gets older. A girl with PKU is particularly likely to face stress in her child-bearing years because of the likelihood of her giving birth to a handicapped child. This risk to the fetus is probably reduced if a low phenylalanine diet is given during pregnancy, although the diet should be introduced before conception and no guarantee of a normal outcome can be given. Finally, because of the higher rates of psychiatric disorder in children with brain dysfunction (Graham and Rutter, 1968), even children in whom PKU is treated early may have an increased risk of disturbance, however strictly the diet is enforced, because blood phenylalanine levels are bound to vary over a wider range than in the normal child. For these reasons it was thought worthwhile to investigate behavioural deviance in children with PKU.

Patients and methods

Newborn infants in the UK are tested for raised blood phenylalanine levels between the 6th and 14th day of life. The Medical Research Council and the Department of Health and Social Security maintain, initially at Alder Hey Hospital, Liverpool, and currently at the Institute of Child Health, London, a phenylketonuria register. Paediatricians and screening laboratories are asked to notify newly diagnosed cases and at yearly intervals paediatricians are asked to provide follow-up details. The organisation of the register has been described by Hudson and Hawcroft (1977). Paediatricians are asked to arrange for IQs to be measured in all the children at 4 years (Stanford Binet) (Terman and Merrill, 1960), and then at 8, 10, and 12 years (Wechsler intelligence scale for children) (Wechsler, 1949), within 6 weeks of each child's birthday; the psychologist carrying out the test at 8 years is also asked to give a Schonell graded word reading test (Schonell, 1955).

Since 1972 paediatricians have been requested to ask parents to complete a behaviour questionnaire (Rutter A scale) of known reliability and validity

(Rutter *et al.*, 1970b) when the child is 8 years old. At the same age, after obtaining parental permission, the child's class teacher is asked to complete a behaviour questionnaire (Rutter B scale) (Rutter, 1967) on the patient and, as controls, on 2 children in the same class of the same sex and nearest in age to the patient. The information on the control children is provided anonymously.

The Rutter parent and teacher scales consist of descriptions of behaviour rated as 'certainly applies', 'applies somewhat', and 'doesn't apply' (scored 2, 1, and 0 respectively). The teacher scale has 26 such items and the parent scale 18; the parent scale has, in addition, 13 items on health and habits (similarly scored 2, 1, and 0). Children scoring 9 or more on the teacher scale or 13 or more on the parent scale, have been shown by Rutter to have a higher risk of psychiatric disorder than those with lower scores. Furthermore, the deviant behaviour shown by children with high scores can be classified into 3 diagnostic types—antisocial, neurotic, or mixed—depending on the ratings of relevant individual items (Rutter *et al.*, 1970b). In the present study because numbers were small, antisocial and mixed groups are combined in the analysis.

The children in the present study are the first 99 children with early treated PKU on the register whose parents had completed a behaviour questionnaire. For 38 other early treated cases no parent behaviour questionnaire had been obtained. Teacher behaviour questionnaire data are also available for this sample and for their 197 matched control children (data were missing for one control child). IQ data were obtained for a subsample of 86 PKU children. Parent scale ratings and IQs were not obtained on control children.

Results

Overall rates of behavioural deviance on the teacher Rutter scale for patient and control groups. Table 1 shows the numbers of patient and control children that were identified by the teacher scale as being behaviourally deviant. More (40%) of the patient sample were behaviourally deviant than the control group (20%) ($\chi^2=13\cdot50$, df=1, $P<0\cdot001$). A greater proportion of the total patient sample (22%) showed neurotic deviance than did the control group (8%) ($Z=3\cdot59$, $P<0\cdot001$). The proportions in the 2 groups showing antisocial deviance were not significantly different.

There is a difference between the boys and girls in the patient sample. The male patients showed more frequent behavioural deviance than the controls ($\chi^2=21\cdot38$, df=1, $P<0\cdot001$) and the proportion of male patients with neurotic deviance (31%) was greater than that of the controls (4%) ($Z=2\cdot15$, $P<0\cdot05$); the proportion of male patients with antisocial deviance although twice that of the controls was not significantly different. For female patients neither the overall rate of deviance nor the rate of antisocial or neurotic deviance was significantly greater than for controls. The greater behavioural deviance among the children with PKU is due mainly to the neurotic deviance among the boys.

Parental Rutter scale rates of deviance for the patient group. The children with PKU showed the same pattern of deviance on the parental scale as was found on the teacher scale. The parents identified fewer children as deviant (24%) than the teachers (40%) ($\chi^2=5\cdot91$, df=1, $P<0\cdot02$) but, like the teachers, they more often identified neurotic deviance than antisocial deviance. On the parent scale boys (33%) again more often showed deviance than girls (17%) and although the rates of antisocial deviance were similar for boys (11%), and girls (7%), the parents identified more boys (22%) than girls (9%) as neurotic. None of these sex differences is however significant.

Table 1 *Rates of behavioural deviance on teacher Rutter scale in patients and controls*

	Not deviant	*Deviant*	*Type of deviance*		*Total*
			Antisocial and mixed	*Neurotic*	
	No. (%)	*No. (%)*	*No. (%)*	*No. (%)*	
Controls					
Total	157 (80)	40 (20)	25 (12)	15 (8)	197
Boys	74 (83)	15 (17)	11 (12)	4 (4)	89
Girls	83 (77)	25 (23)	14 (13)	11 (10)	108
Patients					
Total	59 (60)	40 (40)	18 (18)	22 (22)	99
Boys	20 (44)	25 (56)	11 (24)	14 (31)	45
Girls	39 (72)	15 (28)	7 (13)	8 (15)	54

Rates of behavioural deviance on teacher Rutter scale for children with different IQ levels within the patient group. The mean IQ at 8 years was for boys 89·74 (SD 19·33) and for girls 83·25 (SD 17·72). The product moment correlation between the total score on the teachers scale and IQ for boys was $-0\cdot29$ ($P<0\cdot05$) and for girls $-0\cdot42$ ($P<0\cdot01$).

Table 2 shows that the rates of behavioural deviance for the PKU children vary with IQ measured at 8 years. The IQs of the control children were not measured, so comparison was made between patients in each IQ group and controls undifferentiated as to IQ. PKU boys with IQs<70 show a greater incidence of behavioural deviance (66·7%) than controls (17%) ($\chi^2=9\cdot27$, df=1, $P<0\cdot01$) and are more likely, if deviant, to show neurotic deviance (Fisher's exact probability test $P=0\cdot03$). Patient boys with IQs in the range 70–99 again show more deviance (62%) than controls ($\chi^2=15\cdot88$, df=1, $P<0\cdot001$) but with no significant difference in the type of deviance. Those patient boys with above average IQs (IQ ⩾100) show more deviance (41·7%) than controls, although this difference is not significant. However those PKU boys with IQs>100, if deviant, are more likely than the controls to be neurotic (Fisher's exact probability test $P=0\cdot05$).

For the PKU girls with IQs<70 there is more behavioural deviance (75%) than in the control girls (23%) ($\chi^2=11\cdot86$, df=1, $P<0\cdot001$), but no significant difference in the type of deviance. PKU girls with IQs in the range 70–99 show no significant differences in the rates of deviance or type of deviance from the control girls. However, for PKU girls with average and above average IQs (IQ⩾100) there were no cases of behavioural deviance, compared with 23% for the control girls ($\chi^2=4\cdot21$, df=1, $P<0\cdot01$).

Discussion

The results of the study show that PKU children had significantly higher rates of behavioural deviance than matched controls. The high rate of deviance however is restricted to boys, and to girls with IQs<70. Previous work with the Rutter scales has demonstrated that behavioural deviance is closely related to the presence of psychiatric disorder, defined as a significantly handicapping behavioural or emotional disturbance (Rutter, 1967; Rutter *et al.*, 1970b). The high rate of deviance found among the PKU children of this study probably indicates that these children have a higher rate of psychiatric disorder than normal children. These findings are not in agreement with those of Siegel *et al.* (1968) who used an unstandardised school behaviour profile and compared PKU children with matched controls, finding no greater amount of behavioural deviance in 13 PKU children.

In the present study 20% of control children were rated as behaviourally deviant on the teacher questionnaire. This percentage is high compared with that found in the Isle of Wight (IOW) study (Table 3) but is almost identical with the figure of 19·1% found in a study of randomly selected 10-year-old children living in an inner London borough (Rutter *et al.*, 1975), which is probably representative of children living in big cities in the UK. We do not have data on the urban/rural distribution of the PKU children but it is likely that, as with the general population, most of them live in urban areas.

The rate of 40% deviance on the teacher questionnaire for the children with PKU is higher than any other group of children so far reported, except for IOW children suffering from combined lesions above the brain stem (usually cerebral palsy) with or without epilepsy (Table 3). The rate of 24% deviance

on the parent questionnaire is also similar in children with brain lesions and those with uncomplicated epilepsy and is again higher than all others reported. However the children in the present study were younger than those of other studies, and a previous study (Graham and Rutter, 1973) showed that younger children tend to have higher rates of deviance when measured by the Rutter scales.

Another factor which may have contributed to the high rates of deviance observed in children with PKU is their low IQs. Previous work with normal children has shown a relationship between IQ and behavioural deviance, particularly for the teacher scale. Children with intellectual retardation (IQ <70) on the IOW (Rutter *et al.*, 1970b) showed deviance rates of 41% with roughly equal proportions of neurotic and antisocial deviance, and children with psychiatric disorder have been shown to have slightly lower IQs than normal controls (Rutter *et al.*, 1970b); however the effect is slight (equivalent to about 5 IQ points), and for boys it is restricted to those with antisocial disorders. The high rate of deviance of PKU girls is confined to those with IQs<70, and boys with IQs<70 showed a particularly high rate of deviance. However boys with IQs>70 also showed significantly more frequent behavioural disturbance; this together with the high rate of neurotic disorder among the boys suggests that low IQs cannot be the only explanation for the behavioural deviance.

It is not possible from these data to find the cause for the high rate of behavioural deviance among PKU children, although there are several possibilities, namely: (1) direct effect of raised blood phenylalanine levels on brain cell metabolism producing disordered functioning, (2) effect of phenylalanine levels on brain growth and development in early life, (3) psychological effects of a very abnormal diet for a long period on the child himself or via its effect on family relationships (Keleske *et al.*, 1967; Sibinga and Friedman, 1971; Bentovim, 1976), and (4) a genetic mechanism linking the gene producing PKU with others producing a vulnerability to psychiatric disturbance. Psychiatric disturbance, which the high rate of behavioural deviance implies, is a handicap which the treated child (particularly boys) with PKU is more likely to show than children in the general population; those managing the condition may find it helpful to be aware of this fact.

The Medical Research Council and Department of Health and Social Security provide financial support for the register. We are grateful to the paediatricians, psychologists, parents, and children who have cooperated in the study which is ongoing.

We wish to pay tribute to Dr F. Hudson who, until his death in 1976, was responsible for the running of the PKU register and whose enthusiasm and dedication are responsible for the register now providing a valuable research tool, which should allow much further work aimed at the improvement of the management of patients with PKU.

Intestinal bile salts in cystic fibrosis

Studies in the patient and experimental animal

SUMMARY The quantitative and qualitative distribution of bile salts in the duodenal juice of 13 patients with cystic fibrosis (CF) was studied after a test meal. The effects of triolein (TO), bovine serum albumin (BSA), and ricinoleic acid (RA) on the absorption of taurocholate (TCA) in the distal ileum of the rat *in vivo* was also studied.

The mean (and ranges) of total bile salt concentrations, glycine: taurine conjugate ratios, and percentage of dihydroxy bile salts in the patients with CF and pancreatic insufficiency were 3·5 (1·3–6·6) mmol/l, 8·6 (>10–3·1), and 37 (10–60) compared with control values of 7·4 (3·0–16·0) mmol/l, 3·0 (1·3–4·5), and 61 (52–70) respectively. The differences between the control and CF values were statistically significant ($P<0\cdot01$–$P<0\cdot001$). Three of the 13 CF patients had total bile salt concentrations <2 mmol/l, 8 had much higher glycine: taurine ratios, and 8 had a reduced percentage of dihydroxy bile salts. In 2 patients with normal pancreatic enzyme activities, duodenal bile salts were both quantitatively and qualitatively normal. TO (10 and 30 mmol/l), BSA (3%). and RA (5 mmol/l) had no inhibitory effect on the ileal absorption of TCA.

These results show pronounced abnormalities of duodenal juice bile salts in CF with pancreatic insufficiency consistent with a broken enterohepatic circulation (EHC); such abnormalities may contribute to defective lipid absorption in CF. The data in the experimental animal do not support the suggestion that unhydrolysed dietary substrates play a role in the pathophysiology of the broken EHC.

Recent studies have shown that children with cystic fibrosis (CF) excrete similar amounts of faecal bile salts as patients with ileal resections (Weber *et al.*, 1973, 1976; Goodchild *et al.*, 1975), and on the basis of kinetic studies, this increased faecal loss appears to be secondary to a broken enterohepatic circulation (EHC) of bile salts (Watkins *et al.*, 1974, 1977). The pathogenesis of the broken EHC has not been defined. Weber *et al.* (1973, 1976) reported a significant correlation between faecal fat and bile salt excretion, and found that pancreatic extracts and/or a low fat diet supplemented with medium-chain triglycerides markedly reduced the faecal excretion of bile salts. From these findings they suggested that unhydrolysed triglycerides might impair the ileal absorption of bile salts.

We investigated the total and individual bile salt patterns in the proximal small intestine of children with CF after a test meal, and studied some of the pathophysiological mechanisms that may be responsible for the broken EHC in the rat ileum.

Subjects and methods

Thirteen (6 boys and 7 girls) patients with CF were investigated, their ages varied from 1 to 182 months with a mean of 52·3 months. The diagnosis of CF was established by the finding of sweat Na and Cl concentrations of >70 mmol/l on at least two occasions in volumes of sweat >100 mg. All the patients had typical clinical features, and all except 2 had markedly reduced activities of pancreatic lipase, trypsin, amylase, and esterase compared with control values (McCollum *et al.*, 1977). Pancreatic extracts and antibiotics were discontinued 48 hours before administering the test meal. The control group (6

boys and 4 girls) consisted of children with suspected malabsorption who were proved to be normal after extensive investigation; their ages ranged from 16 to 192 months with a mean of 40 months. None of the subjects had clinical or biochemical (serum proteins, bilirubin, and transaminases) evidence of liver disease.

Details of the test meal and duodenal intubation procedure have been described elsewhere (McCollum *et al.*, 1977). The meal, which was a modification of the Lundh meal, contained carbohydrate (4%) in the form of glucose, protein (4%) as comminuted chicken, and fat (4%) as corn oil; it was administered via a nasogastric tube after an overnight fast in the older children or after a 4-hour fast in young infants. Two-hour postprandial collections of juice were then obtained by siphonage on ice and aliquots of this postprandial pool were analysed.

Total bile salt concentrations in the duodenal aspirates were determined by the enzymatic procedure of Iwata and Yamasaki (1964) using 3-α-hydroxy steroid dehydrogenase (Cambrian Chemicals Ltd) after their extraction on Amberlite XAD-2 resin (Makino and Sjovall, 1972) supplied by British Drug Houses Chemicals Ltd. Individual bile salt concentrations were determined by the same method after separation on thin-layer chromatography using the solvent system of Hofmann (1964); amyl acetate/propionic acid/n-propanol/water (4:3:2:1 by vol). Both procedures gave consistent recoveries of >85%.

Animal experiments. The animal experiments were performed using an *in vivo* closed-loop model as previously described (Harries and Sladen, 1972; Sladen and Harries, 1972). A 20 cm segment of terminal ileum was used in male Wistar rats weighing 250–300 g after an overnight fast, water being allowed *ad libitum.*

All solutions were prepared on the day of the experiment. The solutions were mixed by ultrasound and gassed with 95% O_2 and 5% CO_2 to pH 7·1 immediately before instilling approximately 2 ml into the loop. The control solutions contained 10 mmol sodium taurocholate (TCA) (Koch Light)/l, 1 mmol oleate/l and 0·5 mmol monolein/l (Sigma Chemical Company Ltd), 4 mmol KC1/l, 25 mmol $NaHCO_3$/l, and were made up to 280 mosmol/l with NaCl. ^{14}C labelled taurocholate (Radiochemical Centre, Amersham) was added to give an activity of 1 μCi/ml. The test solutions were of a similar composition to the control solutions but, in addition, contained 10 or 30 mmol triolein (Sigma Chemical Company Ltd)/l, 3% bovine serum albumin (fraction V from Armour Chemical Company), or 5 mmol sodium ricinoleate (Eastman Chemical Company)/l. The stock lipid solutions were made up in organic solvents, and appropriate aliquots were evaporated to dryness under nitrogen before mixing with the bile salt-buffer solution.

After the absorptive period a 100 μl aliquot of the fluid remaining in the loop was counted in 10 ml of a dioxan-based scintillant: naphthalene 70 g, PPO 7 g, POPOP 0·0526 g/l dioxan (Hopkin and Williams Ltd). The solution was counted in a LKB Wallac beta counter with external standardisation.

Statistical analysis. The significance of differences between mean values was assessed by the Student's *t* test.

Results

Duodenal bile salts. Figs 1, 2, and 3 show the values for total bile salt concentrations, the molar ratios of glycine to taurine conjugates, and the percentage of dihydroxy bile salts in the duodenal juice of patients with CF and pancreatic insufficiency compared with controls. Unconjugated bile salts were not detected.

In the controls, the mean (and ranges) of total bile salt concentrations, glycine: taurine conjugate ratios, and percentage dihydroxy bile salts were

O=Controls;
●=CF patients.

7·4 (3·0–16·0) mmol/l, 3·0 (1·3–4·5), and 61 (52–70) respectively. Pronounced differences were found in the CF patients with pancreatic insufficiency, corresponding values being 3·5 (1·3–6·6) mmol/l, 8·6 (>10–3·1), and 37 (10–60); P values were <0·01, <0·001, and <0·001 respectively. Six of these 11 patients with CF had total bile salt concentrations that were below the control range, and in 3 of these the concentrations were less than the critical micellar concentration (i.e. 2 mmol/l). Eight of the 9 patients had markedly increased glycine to taurine conjugate ratios. In six the ratio was 10 or greater, taurine conjugates being undetectable or only present in trace amounts. In 8 of the 9 patients the percentage of dihydroxy bile salts was reduced, and 6 of these patients were less than one year old. There was no apparent relationship between total bile salt concentrations or glycine: taurine ratios and age.

In the 2 patients with normal pancreatic enzyme activities, duodenal bile salts were both quantitatively and qualitatively normal. The total bile salt concentrations were 16·1 and 25·5 mmol/l, the glycine: taurine ratios 4 and 3·5, and the percentage dihydroxy bile salts 56 and 70 respectively.

Animal studies. Preliminary experiments were performed in order to establish the relationship between TCA absorption and the absorptive period, and the results are shown in Fig. 4. Luminal disappearance of TCA was very rapid during the first 30 min. By 30 min the mean percentage absorption of TCA was 89% compared with 77% for the 20-min absorptive period. When expressed as μmol/g wet weight of ileum corresponding mean values for the 1-, 5-, 10-, 20-, 30-, and 40-min absorptive periods were 0·86, 5·77, 9·30, 10·41, 13·74, and 11·20

respectively. For all subsequent experiments a 20-min absorptive period was used unless otherwise stated. In other preliminary experiments the whole loop of ileum was removed, opened, washed with isotonic saline, saponified and counted for radioactivity as described by Dawson and Webb (1973). A constant but small percentage (<5%) of label was present in the tissue, confirming that luminal disappearance reflected absorption of TCA from the loop.

The effect of adding triolein (10 and 30 mmol/l), bovine serum albumin (3%) and ricinoleic acid (5 mmol/l) on TCA absorption is shown in the Table. None of these agents had a statistically significant effect on TCA absorption during the 20-min absorptive period. The effect of triolein (10 mmol/l) was studied at different absorptive periods from 1 to 40 min and had no effect on TCA absorption at any of these times.

Discussion

This study has shown pronounced quantitative and qualitative abnormalities in the distribution of duodenal bile salts in children with CF and pancreatic insufficiency after a test meal compared with control subjects.

The mean ratio of glycine:taurine conjugates (3·0) and the percentage of dihydroxy species (61%) in our control subjects are almost identical with those reported for normal adult bile (Heaton, 1972). The mean age of our control group was 40 months, an age when duodenal bile salts have previously been shown to be similar to those found in adults (Poley *et al.*, 1964). We have previously shown, using the same intubation procedure, that the concentration of total bile salts in duodenal juice varies during a 2-hour postprandial collection (McCollum *et al.*, 1977). In this study determinations were performed on an aliquot of the mixed postprandial collection, thus representing a mean of the postprandial concentration fluctuations. By definition this mean value will overestimate the lowest bile salt concentration during the postprandial period.

Table *Effect of triolein (TO), bovine serum albumin (BSA), and ricinoleic acid (RA) on the ileal absorption of taurocholate (TCA)*

	No. of animals	*Absorption of TCA (µmol/g wet weight ileum per 20 min)*
Controls	7	10·41±1·20
10 mmol TO/l	8	12·85±0·92
30 mmol TO/l	4	10·29±0·96
5 mmol RA/l	3	14·4±0·78
3% BSA	9	17·6±0·83

Absorptive values expressed as mean±1 SE.

Under the conditions of the present study 6 of the 11 CF patients with pancreatic insufficiency had total bile salt concentrations below our normal range, and in 3 the concentrations were below the critical micellar concentration (CMC), if this value is taken as 2 mmol/l. There was a marked increase in the ratio of glycine:taurine conjugates (mean 8·6), and a concomitant reduction in the percentage of dihydroxy bile salts (mean 37%); although these two qualitative abnormalities may be present in non-CF subjects during early infancy (Heaton, 1972), this cannot be the case in our older patients. The CMC is higher for trihydroxy compared with dihydroxy bile salts (Heaton, 1972), and the pKa of glycine conjugates (approximately 4·0) higher than that for taurine conjugates (approximately 2·0). These observations, coupled with the relatively low pH of the duodenal juice in some CF patients, would be anticipated to result in defective micellar solubilisation of lipid in CF, and contribute to the malabsorption of fat. This would be in keeping with the well established fact that pancreatic supplements only partially reduce the faecal losses of fat in most CF patients. Goodchild *et al.* (1975) using a different test meal after hormonal stimulation found mean total bile salt concentrations in duodenal juice to be no different in 5 CF patients compared with 2 adult controls. After stimulation with CCK-PZ and then secretin in the same patients the same authors reported mean bile salt concentrations (mmol/l/per 10 min) as 22·3 and 36·2 respectively. After stimulation with CCK-PZ the mean ratios of total trihydroxy:dihydroxy, and glycine to taurine conjugated bile salts were 1·9 and 5·2 respectively; these ratios show a similar trend to those which we observed although the glycine to taurine ratio in our patients was more pronounced. The marked discrepancies in total bile salt concentrations between the study of Goodchild *et al.* (1975) and ours may be related to technical differences. For example, intravenously administered CCK-PZ provides information on the maximal capacity of the pancreas to secrete its proteolytic juice and on maximal gallbladder contraction; in addition Goodchild *et al.* (1975) reported a reduced volume of duodenal fluid in response to hormonal stimulation, which might be anticipated to result in 'apparently' normal total bile salt concentrations. In the study of Goodchild *et al.* (1975) the test meal was administered soon after IV CCK-PZ and secretin, and bile salt data were reported for periods after both the hormonal stimuli and the test meal. The data after their test meal may not therefore accurately reflect the physiological events which are associated with entry of gastric contents into the proximal small intestinal lumen in CF, but rather the net response to maximal hormonal stimulation in addition to the test meal.

Marked increases in faecal output of bile salts have been reported in young children with CF (Weber *et al.*, 1973, 1976; Goodchild *et al.*, 1975), with reduced output (often within the normal range) in older children and young adults (Goodchild *et al.*, 1975; Roller and Kern, 1977). These observations together with our data are entirely consistent with a broken EHC secondary to defective absorption of bile salts by the distal ileum in young children with CF.

The pathophysiological mechanisms responsible for the broken EHC in CF have not been defined and raise intriguing and fundamental questions concerning bile salt metabolism in general. The ileal absorption of bile salts occurs by an active, carrier-mediated, sodium-dependent transport system which represents a highly efficient biological process for the conservation of the total bile salt pool of the body, and is basic to the maintenance of a normally operating EHC (Dowling, 1972). It has been suggested that the broken EHC in CF results from unhydrolysed triglycerides or other unhydrolysed dietary constituents interfering with the ileal absorption of bile salts (Weber *et al.*, 1973, 1976; Goodchild *et al.*, 1975; Watkins *et al.*, 1977). The finding of increased faecal bile salt outputs in other causes of pancreatic insufficiency lends support to this hypothesis (Goodchild *et al.*, 1975), as does the observation of Weber *et al.* (1973) who reported a good correlation between faecal bile salts and fat. This however, was not confirmed by Goodchild *et al.* (1975). In this context it is of interest that in the 2 patients with normal pancreatic enzymes in our study, duodenal bile salts were quantitatively and qualitatively normal. The relatively high concentrations of total bile salts in these 2 patients may be related to the reduced volume output of pancreatic secretions which occurs in CF, even in the absence of pancreatic insufficiency. The above observations prompted our studies on the possible effects of unhydrolysed fat and protein, as well as an hydroxy fatty acid, on the absorption of a bile salt in the terminal ileum of the rat *in vivo*.

High intraluminal concentrations of triolein, bovine serum albumin, and ricinoleic acid did not influence absorption rates of TCA in the rat ileum (see Table). Although caution should be exerted in extrapolating data from the experimental animal to man, our results do not appear to support the hypothesis that impaired pancreatic hydrolysis of dietary fat and protein (or the production of hydroxy fatty acids) plays a pathophysiological role in the broken EHC in CF.

There are a number of other explanations which can be considered. For example, there may be a defect in the mucosal phase of bile salt absorption which is unrelated to the nature of the luminal contents. This possibility rests on reports which have described increased faecal outputs of amino-acids (Gibbons *et al.*, 1969), impaired *in vitro* uptake of phenylalanine by small intestinal mucosa (Morin *et al.*, 1976), impaired vitamin B12 absorption (Deren *et al.*, 1973), and reduced mucosal lactase activity (Antonowicz *et al.*, 1968) in CF patients. It has also recently been shown using a steady state perfusion technique that the jejunal absorption of phenylalinine, but not lysine, is impaired in CF patients (P. Milla, personal communication). These two amino-acids are probably absorbed by separate transport systems (Matthews and Laster, 1965) which suggests that phenylalanine malabsorption may reflect a selective and primary defect of mucosal function in CF. These anormalities are not likely to be related to gross mucosal damage as the only described alterations of mucosal morphology in CF are dilated mucosal glands (Thomaidis and Arey, 1963) and thickening of surface mucus (Freye *et al.*, 1964). The possibility of a primary mucosal defect is supported by the finding that faecal bile salt losses in children with active coeliac disease are not significantly different from controls (Weber *et al.*, 1973), as the mucosal lesion in coeliac disease is predominantly a proximal one. This is not supported by a recent report in which marked reductions in faecal losses of bile salts were shown in older children and young adults with CF (Roller and Kern, 1977). The reason for the difference in bile salt excretion in older children and young adults compared with younger patients is not at present clear. A progressive reduction in the bile salt pool secondary to inadequate compensatory synthesis of bile salts by the liver is one possibility which requires further study; such a possibility is supported by the increased incidence of gallstones which occurs in older children with CF (Roy *et al.*, 1977). Alternatively more proximal regions of the small intestine may develop an increased capacity to absorb bile salts.

There is evidence that a component of pancreatic juice facilitates the absorption of vitamin B12 in the distal ileum (Toskes *et al.*, 1973), and a similar process could participate in bile salt absorption resulting in excessive faecal losses of bile salts in CF. It is difficult, however, to reconcile this possibility with the observed reduction in faecal bile salt losses which is associated with low fat or medium chain triglyceride diets in CF patients (Weber *et al.*, 1976).

The marked increases in faecal bile salt excretion in CF patients may have major clinical implications to the patient, and the pathophysiological mechanisms responsible for the broken EHC require further elucidation. Our animal studies, however, do not support the hypothesis that defective pancreatic hydrolysis of dietary substrates is responsible for the increased excretion of bile salts in this condition.

Complete deficiency of adenine phosphoribosyltransferase

A third case presenting as renal stones in a young child

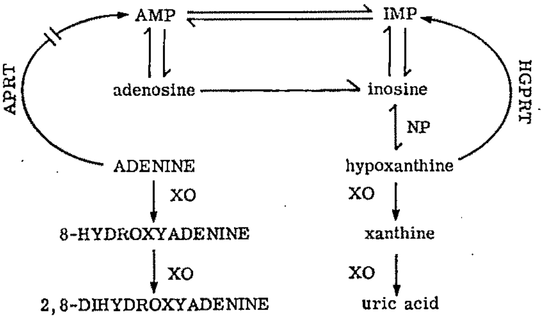
SUMMARY We report a third case of 2, 8-dihydroxyadenine stones in a child with a complete lack of the adenine salvage enzyme—adenine phosphoribosyltransferase (APRT). The propositus, a 20-month-old girl of consanguineous Arab parents, presented with multiple urinary tract infections and supposed 'uric acid' stones in the right renal pelvis and left ureter. Both parents and one brother were heterozygotes for the defect, in keeping with an autosomal recessive mode of inheritance. In contrast with the other purine salvage enzyme disorder of childhood with true uric acid stones (the Lesch-Nyhan syndrome), uric acid excretion was normal in all family members. As in our previous case, treatment with allopurinol, without alkali, has eliminated the urinary excretion of 2, 8-dihydroxyadenine: the stones were removed surgically. 2, 8-Dihydroxyadenine should be considered in any child thought to have uric acid stones and tests made to distinguish the two compounds.

Many urinary stones or crystals identified in children result from the overexcretion of normally minor urinary constituents, compounds of limited solubility whose overexcretion may be the direct consequence of a block in an essential step in a metabolic pathway. Examples are found in hereditary oroticaciduria (Smith *et al.*, 1972), xanthinuria (Dent and Philpot, 1954), and the Lesch-Nyhan syndrome (Nyhan, 1973). In the Lesch-Nyhan syndrome, uric acid stones or gravel form because of gross overproduction of uric acid arising from a lack of the hypoxanthine salvage enzyme–hypoxanthine-guanine phosphoribosyltransferase (HGPRT: EC 2.4.2.8) (Fig. 1). These children also have bizarre neurological complications and other clinical manifestations (Nyhan, 1973).



APRT = adenine phosphroibosyltransferase; HGPRT = hypoxanthine guanine phosphoribosyltransferase; NP = nucleoside phosphorylase; XO = xanthine oxidase; AMP = adenosine monophosphate (adenylate); IMP = inosine monophosphate (inosinate).

Fig. 1 *Metabolic pathways of purine degradation and salvage illustrating the origin of 2, 8-dihydroxyadenine. In the absence of APRT, adenine becomes available for oxidation by xanthine oxidase to hydroxy- then dihydroxyadenine, in a fashion analogous to the production of uric acid from hypoxanthine. In man, adenine cannot be converted to adenosine by nucleoside phosphorylase as hypoxanthine may be converted to inosine, so this route is not available for disposal of adenine. The only alternative pathway is oxidation.*

A complete lack of the other purine salvage enzyme—adenine phosphoribosyltransferase (APRT: EC 2.4.2.7)—was described in children of two separate families, one in France (Cartier and Hamet, 1974; Debray *et al.*, 1976) and the other from our own unit (Simmonds *et al.*, 1976a, b; Van Acker *et al.*, 1977). Children with this deficiency also present with urolithiasis, because of the excretion of 2, 8-dihydroxyadenine, an extremely insoluble analogue of uric acid (Fig. 1). The excretion of this compound follows the accumulation of adenine in the absence of the salvage enzyme, APRT, and its oxidation by xanthine oxidase via the 8-hydroxy intermediate (Fig. 1) (Bendich *et al.*, 1950).

We report studies in a third family with a complete lack of the APRT enzyme. Stones of 2, 8-dihydroxyadenine were present in the daughter. As in the two previous cases, the stones were first mistaken for uric acid because 2, 8-dihydroxyadenine and uric acid are indistinguishable in chemical tests used routinely for identifying uric acid stones (Simmonds *et al.*, 1978).

Clinical data

The patient was born in August 1975, the 3rd child of consanguineous Arab parents (Fig. 2). Birth was normal and she was well until aged one year, when she began to suffer repeated attacks of abdominal pain and fever. These were diagnosed as urinary tract infections and, in May 1977, she was referred, aged 21 months, for investigation of lithiasis. An IVU showed a nonfunctioning left kidney, and a radiolucent calculus in the pelvis of the right kidney (Fig. 3). She was 81 cm in height, 10·0 kg in weight, and had red hair. Neither kidney was tender or palpable, and neurological examination was normal. However, urine culture showed a growth of $>10^5$ *Klebsiella aerogenes*/ml, with numerous leucocytes, red cells, and debris. Hb was 11·6 g/dl, WBC 14 400 /mm^3 (14·4 × 10^9/l). Plasma electrolytes were normal, with blood urea 4·5 and 3·4 mmol/l (27 and 20 mg/100 ml). Plasma creatinine was initially 40 μmol/l (0·45 mg/100 ml), but later was 100 and 120 μmol/l (1·13 and 1·36 mg/100 ml). Serum urate was 0·24 mmol/l (4 mg/100 ml) by a nonspecific colorimetric method. The differential diagnosis of uric acid, or 2, 8-dihydroxyadenine urolithiasis was considered.

At the 1st operation (May 1977) cystoscopy and ureteric catheterisation showed a block in the left ureter 2 cm from the bladder. This calculus was removed by ureterolithotomy, and the stone in the pelvis of the right kidney was removed later at the same operation. Both stones were friable and greyish in colour. The urinary infection was treated with cephalexin 125 mg four times a day.

Examination of the stones by thermogravimetric analysis (Rose and Woodfine, 1976) suggested uric acid, but further examination by wet chemistry (Westbury and Omenoger, 1970) and by other specific techniques (see Methods) showed them to be composed of almost pure 2, 8-dihydroxyadenine (Simmonds *et al.*, 1978). Studies of urinary purines

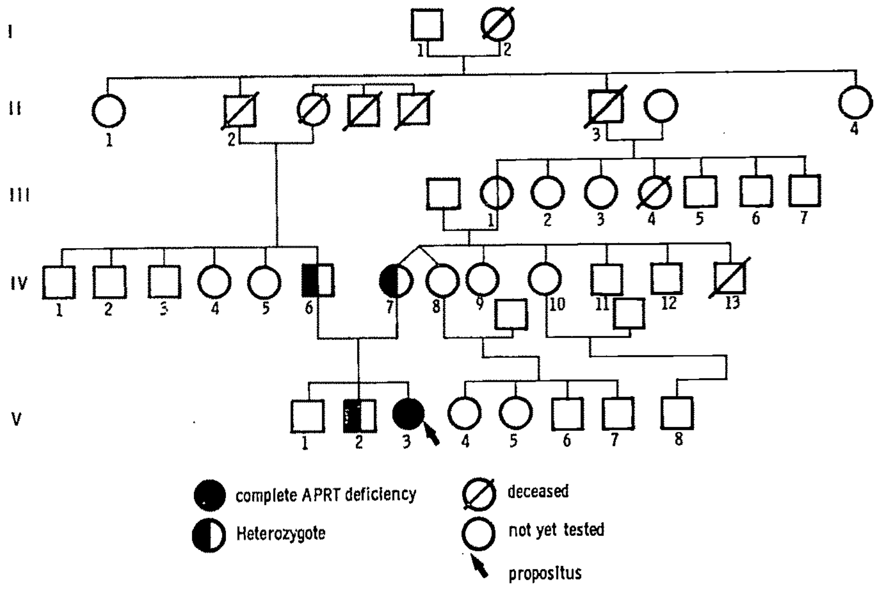

Fig. 2 *The family of the propositus. None of the other members of the family has dihydroxyadenine stones, but only the immediate family was tested for APRT activity (Table 2). Consanguinity is present, the father's grandparents and and the mother's great-grandparents being the same.*

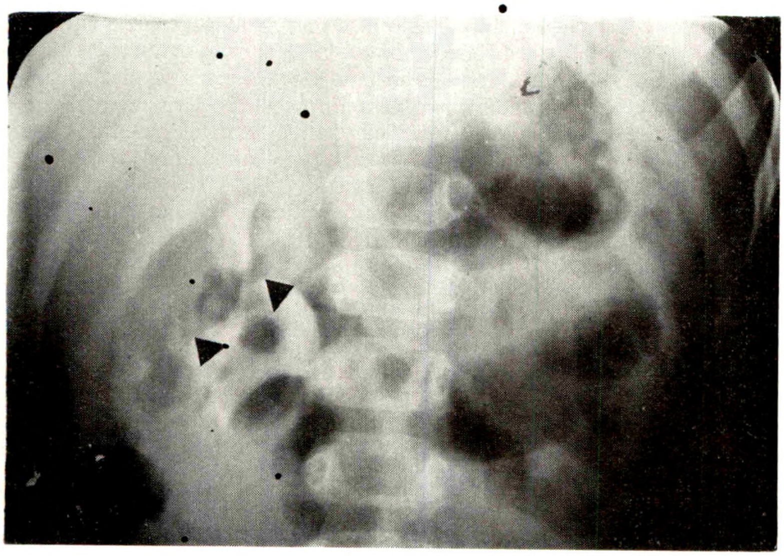

Fig. 3 *IVU taken in May 1977 when patient was aged 21 months. The left kidney does not function at all, and there is a large radiolucent stone (arrow) in the pelvis of the right kidney.*

and purine enzyme activities showed complete lack of APRT (see Methods and Results).

The child was treated with allopurinol 10 mg/kg per 24 h and she returned home. Three months later, in August 1977, she returned for more extensive examination. In the interval she had had several more urinary tract infections, treated with cephalexin and nitrofurantoin. In two of these, *Kl. aerogenes* was again grown from the urine, and in the 3rd attack—*Escherichia coli*. Otherwise she was well and had grown 1·6 kg, and 4 cm in height. Examination of renal function showed a glomerular filtration rate of 90 ml/min per 1·73 m², with only 13% of renal function from the left kidney, as judged by scanning with DMSA. Plasma creatinine was 50, 46, and 56 μmol/l (0·56, 0·52, and 0·63 mg/100ml) and blood urea 3·0, 4·1, and 6·0 mmol/l (18, 24, 36 mg/100 ml). Urine culture showed *Klebsiella*. IVU and micturating cystography showed a doubtful calculus in the right renal pelvis, and several stones in a grossly refluxing left ureter and pelvis (Fig. 4).

At the 2nd operation the left renal parenchyma appeared reasonably well preserved, and the stones were removed from the left by ureter pyelolithotomy and ureterolithotomy. A stricture at the site of the previous removal of stone from the left ureter was repaired. At a 3rd operation (September 1977), retrograde catheterisation of the right urinary tract showed 2 stones in the pelvis of the right kidney similar to those removed previously: these were extracted.

The *Klebsiella* infection was again treated with cephalexin, followed by co-trimoxazole, and the allopurinol dosage increased to 20 mg/kg per 24 h; on this dose the urine became free of 2, 8-dihydroxyadenine. Because of the risk of xanthine or oxipurinol calculi, this dosage was later reduced to 15 mg/kg per 24 h, and the child returned home on this treatment.

During the period of investigation of the propositus, her father suffered from an episode of renal colic, but the stone passed was subsequently identified as pure calcium oxalate.

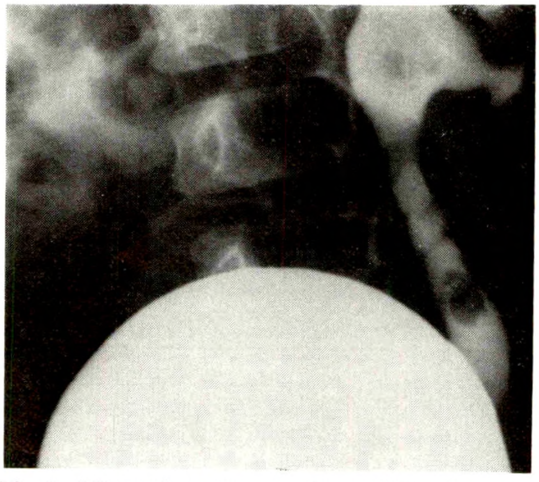

Fig. 4 *Micturating cystogram, August 1977, when patient was aged 24 months. There is reflux of contrast medium into the left urinary tract, and several stones are present in the pelvis and ureter. There is also a ureteric stricture at the site of previous stone removal.*

Methods

Stone analysis was carried out by methods already reported (Simmonds *et al.*, 1976 a, b; Rose and Woodfine, 1976). Methods used in the identification and quantitation of urinary purine metabolites by chromatography and 2-dimensional high-voltage electrophoresis have also been reported previously (Simmonds, 1969). A new rapid and simple method, isotachophoresis of the urine, has also been investigated (Simmonds *et al.*, 1978; Sahota *et al.*, in preparation) and appears to have potential for screening for homozygotes for APRT deficiency.

APRT activity was estimated in both intact (Dean *et al.*, 1978) and lysed erythrocytes, as previously described (Cartier and Hamet, 1968; Van Acker *et al.*, 1977). Blood from the child, her parents, and from her two brothers (aged 12 and 9 years) was taken in the fasting state and centrifuged and separated immediately. 24-hour urine collections were made on a low-purine, caffeine-free diet with toluene as preservative. A 15-hour water deprivation test was performed.

Routine biochemistry was investigated using a Vickers multichannel automated analyser. Complement components C3 and C4 were assayed by radial immunodiffusion using monospecific antisera; haemolytic complement by a plate assay incorporating EA, and serum lipid levels were also measured by standard automated procedures. Lymphocytes were obtained from our patient and her parents; transformation in response to stimulation with PHA, pokeweed and concanavalin A were studied using ^{3}H-thymidine incorporation as indicator of response (Panayi and Corrigall, 1977).

Results

Urinary purine metabolites. Detailed results of the stone identification have been reported (Simmonds *et al.*, 1978).

Urinary purine levels on four separate occasions in our patient are given in Table 1. Total adenine metabolites in each varied between 34 and 28% of the total purine metabolites, the latter being normal when expressed as mmol/kg per 24 h. Plasma uric acid levels were normal in our patient (Table 2) and in her parents on a low purine diet. Urinary uric acid levels were normal in the child, but at the upper limit of normal for her parents. Plasma uric acid levels were also normal in the two brothers (Table 2). Ultraviolet scans obtained using separation of

urinary purines by isotachophoresis (not shown) showed the presence of the abnormal and diagnostic metabolite adenine only in the case of the homozygote; the scan in her case, as in the previous homozygotes, being otherwise indistinguishable from that of a healthy control (Simmonds *et al.*, 1978).

Effect of allopurinol therapy. Total allopurinol metabolites are also given in Table 1; the percentage of the administered dose absorbed and excreted being relatively constant (67–74%) and similar to that in the previous case studied by us (Simmonds *et al.*, 1977; Van Acker *et al.*, 1977) and in healthy controls (Simmonds, 1969). At a dose of 10 mg/kg per 24 h the principal metabolite of allopurinol was oxipurinol. At the higher dose (20 mg/kg per 24 h) increased amounts of unchanged allopurinol and its riboside were detected in the urine, indicating effective inhibition of xanthine oxidase at this dosage. In agreement with this was the absence of detectable 2,8-dihydroxyadenine excretion at the higher dosage. This was accompanied by an increment in the urinary adenine levels, as anticipated, but without any reduction in total purine excretion, in contrast with the situation in a control child, both as noted in our previous case (Van Acker *et al.*, 1977).

Other investigations. Other biochemical investigations, including fasting serum cholesterol and triglyceride concentrations, were essentially normal. The results of the lymphocyte transformation studies were within the lower limit of the normal range for adults in the case of the heterozygotes, and apparently normal for a child of the age of our patient as were complement levels (C3, C4, and total haemolytic complement) in all family members.

Water deprivation tests showed a normal ability to concentrate the urine above 900 mmol/kg in the father and the two brothers. The mother's result was slightly lower, while the patient showed a complete inability to concentrate the urine, compatible with her urinary tract infection and stones. Renal function, as measured by creatinine clearance, was not reduced in other members of this family.

Discussion

This patient is the third in whom 2, 8-dihydroxyadenine stones have been identified as a result of a complete lack of the salvage enzyme—APRT. In all three patients the stones were initially confused with uric acid stones. A brother of the second patient was asymptomatic, although he, too, lacked the enzyme, suggesting that the defect was relatively benign in that it can occur without clinical manifestations. Studies in this third patient have confirmed this and show that children with this defect are clinically normal, apart from having urolithiasis. Correction of their renal complication will allow them to lead a normal life, unlike children with the Lesch-Nyhan syndrome.

Partial APRT deficiency has been described in five separate families, but these cases were discovered during screening for HGPRT deficiency. The association between partial APRT deficiency, gout, and hyperuricaemia, described in some of these families, now appears fortuitous (Kelley *et al.*, 1968; Delbarre *et al.*, 1974; Emmerson *et al.*, 1974, 1975; Fox and Kelley, 1974). Two recent reports (Emmerson *et al.*, 1977; Fox, 1977), have put the incidence of heterozygosity for APRT deficiency at somewhere between 0·5 and 1%.

The discovery of another patient with complete lack of APRT so soon after our other one suggests that the condition may previously have been misdiagnosed, and is more common than its description suggests (Cartier and Hamet, 1974; Simmonds *et al.*, 1976a; Van Acker *et al.*, 1977). The urinary metabolites excreted by the child, as in the previous cases, are a direct consequence of the enzyme defect; in the absence of the APRT enzyme the only alternative metabolic route for adenine is oxidation by xanthine oxidase via the 8-hydroxy intermediate to the extremely insoluble 2, 8-dihydroxyadenine (Fig. 1). Because of its similar structure (Fig. 1) it reacts mole for mole as uric acid during routine chemical testing; hence its frequent misdiagnosis.

An interesting observation, previously noted in both the other affected children and now confirmed, is that total purine end-product including uric acid appears essentially normal. This is surprising in view of the fact that adenine nucleotides with guanine nucleotides have been considered to exert feedback inhibitory control of *de novo* purine production; and absence of the analogous enzyme, HGPRT, in the Lesch-Nyhan syndrome is associated with gross overproduction of uric acid. The normal results in APRT deficiency would suggest that endogenous adenine production is neither extensive nor critical for the overall control of purine production in man. This is in keeping with a dietary origin suggested for the adenine in this defect (Simmonds *et al.*, 1977; Van Acker *et al.*, 1977).

Correction of the urolithiasis in this defect will allow the children to lead a normal life, unlike children with the Lesch-Nyhan syndrome in whom treatment did not lead to an improvement in the mental or neurological parameters. Interestingly, the father of our patient, as did the father of our previous patient, suffered an episode of renal colic with the passage of oxalate stones. The urinary uric acid level in both men is in the upper limit of normal. Xanthine

UNIVERSITY ... LIBRARY

oxidase inhibition will obviously prevent 2, 8-dihydroxyadenine formation (Fig. 1) and allopurinol, a xanthine oxidase inhibitor, will therefore be the drug of choice. The common practice of alkalinisation of the urine for uric acid stones (De Vries and Sperling, 1975) will be ineffective in 2, 8-dihydroxyadeninuria, as the solubility of this compound does not alter within the physiological pH range (Debray *et al.*, 1976). It may even be harmful, since allopurinol plus alkali was ineffective in controlling stone formation in our previous patient (Van Acker *et al.*, 1977), whereas allopurinol alone at a dose of 10 mg/kg per 24 h resulted in immediate cessation of stone formation and crystalluria. A higher dose, 20 mg/kg per 24 h, was necessary to produce the same effect in our present patient, but this may have been due to the presence of stones not removed at the initial operation, in the meantime she is being treated with an intermediate dose, 15 mg/kg per 24 h. As the excretion of adenine metabolites was much greater when our previous patient was on a high rather than a low purine diet we also suggest that a low purine diet be given together with appropriate allopurinol dosage. This may be important as free adenine is not normally present in man for any length of time. APRT-deficient children being treated with allopurinol are testing the *in vivo* toxicity of free adenine. They should therefore be watched carefully, and undergo frequent checks for alteration in any other clinical or biochemical parameters.

Enzyme studies in erythrocyte lysates have confirmed heterozygosity in the parents and the complete deficiency in the child. One brother is also heterozygous, which would be in keeping with the autosomal mode of inheritance suggested in previous studies (Emmerson *et al.*, 1977; Van Acker *et al.*, 1977).

Studies in intact erythrocytes have shown that at normal physiological concentrations of adenine, heterozygotes are indistinguishable from normal individuals; while at higher substrate concentration results comparable with those in erthrocyte lysates are obtained (Dean *et al.*, 1978). This would explain why heterozygotes are essentially normal, since they can cope with normal loads of dietary adenine.

The reason why 2, 8-dihydroxyadenine stones were confused with uric acid stones is the subject of a separate report (Simmonds *et al.*, 1978). Even if specialised techniques are not available, the following clues may help to distinguish children with the defect: uric acid stones are hard and yellow, while 2, 8-dihydroxyadenine stones are friable and greyish-blue on crushing. Uric acid levels in plasma and urine will also be normal in 2, 8-dihydroxyadeninuria. The children are otherwise clinically normal, and have no neurological symptoms or signs. We suggest that any child who is thought to have uric acid stones should have stones and urine examined more closely. If possible, the stones should be submitted for specialised confirmatory studies.

The lungs in congenital bilateral renal agenesis and dysplasia

ALISON HISLOP, EDMUND HEY, AND LYNNE REID

Department of Experimental Pathology, Cardiothoracic Institute, Brompton Hospital, London

SUMMARY A detailed quantitative analysis was made of the lungs from 8 infants dying with bilateral renal agenesis or dysplasia. Total lung volume was reduced in all cases, particularly in those with renal agenesis. In both groups there was a reduction in number of airway generations, indicating interference with development at between 12 and 16 weeks' gestation. The alveoli in each acinus were reduced in size and, in some cases, number—although their stage of differentiation was normal for age—pointing to a disturbance of growth during later fetal life also. As liquor is largely non-renal in origin at least up to 16 weeks' gestation, it seems that there are factors other than the oligohydramnios interfering in early lung growth in these cases, such as reduced proline production by the kidney.

The concurrence of bilateral renal agenesis and pulmonary hypoplasia was first recognised by Potter (1946) and later confirmed by others (Davidson and Ross, 1954; Sylvester and Hughes, 1954; Carpentier and Potter, 1959; Potter, 1965). Later it became apparent that lethal pulmonary hypoplasia was also a consistent feature in babies with no renal function at birth because of bilateral renal dysplasia with or without cyst formation (Ashley and Mostofi, 1960; Bain and Scott, 1960). The underlying mechanism remains obscure although many have suggested that the pulmonary hypoplasia is secondary to oligohydramnios and thoracic compression *in utero*. Siblings are only rarely affected (Buchta *et al.*, 1973; Whitehouse and Mountrose, 1973; Cain *et al.*, 1974; Hack *et al.*, 1974) and there are few reports of both members of a twin pair being affected (Mauer *et al.*, 1974). Oligohydramnios is almost universal, breech presentations and premature labour are frequent, stillbirth is not uncommon (Ratten *et al.*, 1973), and early neonatal death due to respiratory insufficiency is almost inevitable in those born alive. Babies surviving for any time often develop a complicating pneumothorax or pneumomediastinum (Liberman *et al.*, 1969; Renert *et al.*, 1972; Stern *et al.*, 1972; Bashour and Balfe, 1977) and a chest *x*-ray taken at this time may be almost diagnostic (Leonidas *et al.*, 1975). In a series of 49 cases of bilateral renal agenesis, Potter (1961) found at necropsy that the degree of pulmonary hypoplasia varied, but in extreme cases alveoli were almost completely lacking. Reale and Esterly (1973) found a reduced lung to body weight ratio in 20 infants with a variety of renal anomalies. This was greatest in those cases with bilateral agenesis. They also found in some, a reduction in the number of alveoli within each acinus, assessed by the method of Emery and Mithal (1960).

The nature of the hypoplasia in the lungs from infants with congenital diaphragmatic hernia (Kitagawa *et al.*, 1971) and rhesus isoimmunisation (Chamberlain *et al.*, 1977) was analysed by precise morphometric techniques after injection of the pulmonary artery and inflation of the lung. In both conditions the number of airway generations and their accompanying arteries are reduced as well as the total number of alveoli. In the present study, these quantitative methods have been applied to lungs from infants with bilateral renal agenesis or dysplasia. Using these methods, it is possible to analyse type and degree of hypoplasia and the timing of interference with development.

Case material

The lungs from 8 patients with abnormal kidneys were studied and the diagnosis and main features are shown in Table 1. Cases 1 and 2 had bilateral renal agenesis. Case 1 also had sacral agenesis, gross rotation of both lower limbs, and rectal atresia. Three infants (Cases 3–5) were diagnosed as having the typical features of sirenomelia (Duhamel, 1961) which included in these cases bilateral renal agenesis. Cases 1–5 are all referred to as having renal agenesis. Cases 6–8 had renal dysplasia, the kidneys consisting of a mass of watery cysts with no renal tissue (Pathak and Williams, 1964). Case 7 also had hydrocephalus and was thought to have the Dandy-Walker syndrome (D'Agostino *et al.*, 1963). Case 6 was one of twins, the other being anencephalic. In all patients it was reported that little or no liquor was present at birth and amnion nodosum (Landing, 1950) was proved in Cases 1, 2, 5, 7, and 8. All 8 showed evidence of postural moulding. Two babies were stillborn, 5 died of respiratory insufficiency, and one (Case 7) from intracranial haemorrhage. The longest period of survival was 18 hours.

The 2 infants with renal agenesis born before the 31st week of gestation were of normal weight for age but the weight of the others with agenesis was reduced to the 5th centile or less. The infants with renal dysplasia were of normal body weight, except for Case 6 which was on the 10th centile, probably because it was one of twins. In the 4 infants in which it was measured, combined heart and lung weight was reduced. Pressure-volume curves (Reynolds *et al.*, 1968), obtained on all but Case 4, showed that all lungs were reduced in volume, particularly those with renal agenesis. The relationship of volume to pressure change was normal in Cases 2, 3, 7, and 8 showing normal alveolar stability. In Cases 1, 5, and 6 although there was some residual air indicating that surfactant was present, there was a relatively rapid decline in volume with decreasing pressure.

Methods

The pulmonary arteries of the 8 cases were injected with a barium sulphate and gelatine suspension at 60°C and at a water pressure of 100 cm. Arteries were filled and fully distended down to precapillary level. The airways were inflated with buffered formol saline at a pressure of 45·5 cm water and the lungs and heart left to fix for at least one week. The lungs were studied, using quantitative techniques as described by Hislop and Reid (1970). These studies included measurement of inflated lung volume, measurement of lung length and pulmonary artery size on arteriograms, and tracing airway branching pattern by serial reconstruction. The maturity of the alveoli was assessed, size was estimated from the number per unit area, and to estimate alveolar number per acinus the radial alveolar count, as described by Emery and Mithal (1960), was used. Wall thickness of pulmonary arteries was measured and the degree of extension of muscle along the arterial pathways assessed by identifying arteries according to their accompanying airways and their size (Davies and Reid, 1970). After fixation, the hearts were dissected and weighed using the method of Fulton *et al.* (1952).

Results

The morphological findings are summarised in Table 2.

↑—increase in size, number or extension to the periphery; ↓—decrease in size, number or extension to the periphery.

Lung volume. All lungs were greatly reduced in volume. In Cases 1–5 the reduction was greatest, the volume being similar to that of a fetus of about 24 weeks' gestation, and in none was it more than one-quarter of the expected volume. In Cases 6–8 the volume was equivalent to the normal lung at 28 weeks' gestation. In all cases lung length was appropriate for volume.

Airways. In Cases 2, 3, 7, and 8 the posterior basal airway to the left lower lobe was traced from hilum to terminal bronchiolus by dissection and microscopical serial reconstruction. While the normal number of airway generations for this segment is 20–25 (Hayward and Reid, 1952), in all 4 pathways the number was reduced to between 16 and 20 generations. It seemed that the bronchi (the airways which develop first and have cartilage in their wall) were normal in number while the bronchioli (which appear later and lie distal to the cartilage plates) were considerably reduced. Unlike the others, Case 7 had a more nearly normal number of bronchioli. In addition, in Cases 1–5, microscopical examinations showed bronchi abnormally close to the pleura, indicating relative reduction in volume of the respiratory region and of the number of peripheral airways. In Cases 1 and 2, the cartilage plates were large for the size of the airways. In Cases 6–8 distribution of airways was normal.

Alveoli. The development of the alveoli was assessed by their stage of maturation, their number, and size. Judged by gestational age, the lungs should have been in the terminal sac stage of development (Boyden, 1975). At the beginning of this stage, at 24 weeks' gestation, the saccules are simple in outline; by its end, at birth, primitive alveoli are seen in their walls as shallow indentations. In all lungs the alveoli were of normal type for age but were smaller than normal.

Radial alveolar counts showed that in Cases 2, 4, 5, 7, and 8 the number of alveoli in each acinus was more than 1 SD below the normal mean (Emery and Mithal, 1960). In the other 3 cases it was below the mean but within the normal range. As the reduced number of airway generations means a reduced acinar number, it may be assumed that in all lungs the total number of alveoli must be reduced. Thus reduction in alveolar number and size both contribute to the reduced total lung volume.

Pulmonary arteries. From the arteriograms, the overall branching pattern and size of the pulmonary arteries were assessed (Fig. 1).

In Cases 2 and 3 the arteries were normal in size for age of the fetus. In the other 6 lungs the arteries were reduced in size for age, although in each the arteries were large for the volume of the lung. This relative increase was greater in the infants with renal agenesis and in these the arteries appeared large, tortuous, and crowded. This was confirmed microscopically, where large vessels were found close to the pleura. The arteriograms of the renal dysplasia lungs showed normal distribution of vessels and no relative increase in size of peripheral arteries.

Arteries accompany airways and the reduction in the total number of preacinar conventional arteries mirrored reduction in airway number. Supernumerary arteries were present but appropriately reduced in number. The number of arteries per unit area within the acinus was less than normal in the lungs associated with renal agenesis but seemed normal in those with renal dysplasia.

Muscularity of pulmonary arteries. In cases of agenesis (Cases 1–5) the wall thickness of the pulmonary arteries was less than the normal fetal level except in one, the youngest, in which it was at normal fetal level. In case 2 the walls were as thin as in a normal adult—1–2% in the larger vessels.

(*b*)

Figure. *Arteriogram of the lung of* (*a*) *Case 2* (*renal agenesis*) *and* (*b*) *Case 8* (*renal dysplasia*) (× *1*). *The arteries have been injected with a radio-opaque medium.*

In two cases of dysplasia (Cases 6 and 8) wall thickness was at normal fetal level and in the 3rd it was thicker than normal. This case also had an increase in pulmonary vein wall muscle while in all others vein walls were normal.

Muscularity was also assessed by estimating the size of vessels with muscular walls and also the level within the lung to which muscular arteries extended. The pattern of muscularity did not correlate with renal diagnosis nor did it correlate with alveolar development. In 4 patients with agenesis and 2 with dysplasia, the muscle extended into smaller and more peripheral vessels than normal. One patient with agenesis and one with dysplasia had normal muscle distribution by size but less muscle within the acinus, and one patient with agenesis had less arterial muscle, both by size and position, than normal.

Heart weight. The ventricles of the heart were dissected and weighed and the ratio between weight of left ventricle plus septum and right ventricle estimated. In all patients the ratio was in the normal fetal range, between 1 and 2 (Hislop and Reid, 1972a). Total heart weight was less than expected for gestational age in 3 of the 5 patients with renal agenesis and in 2 of these it was reduced even for the reduced body weight. Of the 3 infants with renal dysplasia, heart weight was normal in 2 and reduced in the 3rd but this infant was small, being a twin, and the heart to body weight ratio was normal.

Discussion

These cases with renal agenesis or dysplasia are further illustrations of Potter's observation that the lungs from infants with bilateral renal agenesis are hypoplastic (Potter, 1946). Precise morphometric techniques have now made it possible to analyse separately the several structural constituents of the lung and to detect the presence and define the degree of hypoplasia in each. The abnormality can be interpreted according to the schedule of normal fetal development previously described (Bucher and Reid, 1961; Hislop and Reid, 1972b). Although many of the changes in the lungs were similar in patients with either agenesis or dysplasia, there were features sufficiently different to suggest that in these two conditions the severity or timing of interference may have been different or even that a different factor may have operated.

Pathological changes. Total lung volume was reduced in all cases but particularly so in patients with renal agenesis. Reale and Esterly (1973) found that cases with bilateral renal agenesis had the lowest lung weight/body weight ratio when compared with other types of kidney anomalies. In the present series however, lung volume/body weight ratio was similar in both groups.

Airways and alveoli. The reduction in number of airway generations suggested an arrest in development at between 12 and 16 weeks' gestation because only the broncholi were affected (Bucher and Reid, 1961). It may be that the precise time of effect or the degree of sensitivity at this time explains the greater reduction in renal agenesis. In both groups the drop in airway number must lead to a reduction in number of acini. In the babies with renal agenesis, growth within the acinar region as well as of airways was thought to be reduced because microscopically the respiratory region was small even for the reduced airway number, and the cartilage plates and airways were disproprortionately large when related to lung volume. A relatively greater reduction in the respiratory region has also been reported in one case of thoracic dystrophy by Finegold *et al.* (1971) and in congenital diaphragmatic hernia by Kitagawa *et al.* (1971). The disproportion was not seen in the dysplastic patients. In all lungs the reduced respiratory region was due partly to fewer acini because of fewer airway generations and partly to the small size of alveoli; in 5 cases, in addition, the number of alveoli per acinus was clearly reduced.

In infants with renal agenesis, Potter (1965) described in uninflated lungs, immaturity of the alveolar region, some lungs apparently having no alveoli at all. In the present series there was normal maturity of alveoli.

Arteries. In both renal agenesis and dysplasia, arterial number was reduced and probably followed the reduction in number of airways. In agenesis the arteries were also disproportionately large. In renal agenesis pulmonary arterial wall thickness was less than normal fetal levels. This could reflect a difference in haemodynamic behaviour before birth or an effect on arterial growth other than that associated with size.

Pathogenesis of lung hypoplasia. In the past it has only been possible to discuss the nature and severity of the lung hypoplasia associated with renal disease in terms of the role of amniotic fluid, lung fluid, and urine production; and the explanations were not entirely satisfactory.

In a retrospective study of 31 cases with renal anomalies Perlman and Levin (1974) found that 21 of these had oligohydramnios associated with hypoplastic lungs; the remainder with normal lungs had normal amniotic fluid.

In 2 cases of prolonged leakage of amniotic fluid reported by Perlman *et al.* (1976) the number of alveoli present at birth was the normal expected number at the time of onset of the leakage, suggesting that no further development occurred after fluid was withdrawn. It is pressure of the uterine wall, due to lack of fluid, which is likely to produce the Potter facies and the limb malformations but restriction of the thoracic cavity is unlikely to cause lung hypoplasia as the chest wall is never badly deformed in renal agenesis.

Recent experiments by Alcorn *et al.* (1977) have shown that drainage of the fluid from fetal lamb lungs during development *in utero* leads to a decrease in lung volume and lung tissue with abnormal maturation of the alveolar wall. The reduction in peripheral lung tissue in the present series may be due to excessive drainage of fluid from the lung in the absence of amniotic fluid. In the lamb the lung normally contributes about one-third of the amniotic fluid (Strang, 1977).

The contribution of the kidney to the liquor is important only relatively late in pregnancy (Saunders and Rhodes, 1973). Findings in the present series suggest that because the airway number implied an interference with growth before 16 weeks' gestation, oligohydramnios is unlikely to be the sole cause of lung hypoplasia.

The absence of the kidneys in the cases of agenesis may have a direct but unidentified effect on the lungs. Experimental nephrectomy in fetal lambs has an effect on subsequent fetal growth with a reduction in the glycogen reserves of the liver (Thorburn, 1974). Unfortunately, the lungs were not studied in these experiments.

During fetal development the kidney appears to be an important source of proline: it contains an arginase that influences proline production through an arginine ornithine proline cycle. Clemmons (1977) injected nephrotoxins into chick embryos at various times and followed the effect on the production and metabolism of ^{14}C labelled proline. Decreased ability to metabolise proline was associated with decreased collagen formation. Because it grows actively during the times chosen, he studied the morphological state of the lung, and found it became hypoplastic with sparse mesenchyme. The association of a renal defect and lung hypoplasia can now be interpreted in the language of biochemical and metabolic processes and this offers new ways of investigating the interaction between the kidney and the lung.

In renal dysplasia, lung volume and alveolar and airway size and number are reduced but the cases vary in their severity. In renal agenesis these changes are more pronounced and are associated in addition with disproportionately larger airways and arteries, the latter also having thinner walls. The fact that more severe hypoplasia is seen with renal agenesis than with dysplasia may reflect either a greater reduction in available proline or a difference in the time-table of interference.

Cows' milk protein-sensitive enteropathy

An important contributing cause of secondary sugar intolerance in young infants with acute infective enteritis

N. IYNGKARAN, K. DAVIS, M. J. ROBINSON, C. G. BOEY, E. SUMITHRAN, M. YADAV, S. K. LAM, AND S. D. PUTHUCHEARY

University Hospital, Kuala Lumpur

SUMMARY The effect of cows' milk protein (CMP) on the mucosal disaccharidases was investigated in 23 infants with acute infective enteritis. Jejunal biopsies performed before and after cows' milk provocation were subjected to histological examination and to mucosal disaccharidase enzyme (lactase, sucrase, and maltase) analyses. After milk challenge, changes in mucosal histology were observed in 18 infants, in 17 of them the levels of all 3 mucosal disaccharidases were much reduced. 10 of these infants developed diarrhoea and, in 6, the stools were positive for reducing sugar. It is concluded that CMP has a deleterious effect on the jejunal mucosa of young infants recovering from infective enteritis, so that in the management of young infants with sugar intolerance secondary to infective enteritis, CMP and lactose should be excluded from the diet.

Secondary sugar intolerance is a well recognised and common complication of acute infective enteritis (AIE) in young infants (Burke, *et al.*, 1965; Lifshitz *et al.*, 1971; Chandrasekaran *et al.*, 1975). The intolerance appears to be due to depletion of mucosal sugar-splitting enzymes secondary to damage to the small bowel mucosa caused by the primary infective agent (Weijers and Van de Kamer, 1962; Barnes and Townley, 1973). Exclusion of this sugar, however, does not always affect the diarrhoea. Recently cows' milk protein sensitive enteropathy (CMPSE) was shown to be an important factor prolonging diarrhoea in young infants with AIE (Iyngkaran *et al.*, 1978a). The present study was undertaken to determine the effect of cows' milk protein (CMP) on the intestinal oligosaccharidases in infants recovering from AIE.

Materials and methods

23 infants under age 12 months presenting with the clinical features of AIE, admitted to the Department of Paediatrics, University Hospital, Kuala Lumpur between March 1976 and March 1978 were studied. Investigations on admission included examination of the stools under the light and electron microscope for *Giardia lamblia* and virus, stool cultures for bacterial pathogens, and testing of stools for sugar by the method of Kerry and Anderson (1964).

After appropriate correction of fluid and electrolyte imbalances the infants were started on a formula free of CMP—such as Prosobee, Nutramigen, or Pregistimil (Mead Johnson). All infants remained in hospital until their stools were normal, they were feeding well, and were gaining weight. They were then discharged home, usually within 2 weeks of admission, the mothers being supplied with the appropriate CMP-free formula and instructed not to offer any other milk without first consulting us. About 6 or 8 weeks later the infants were readmitted for further study.

Further study.

Low-lactose cows' milk provocation test*

In most infants 'Al 110' (Nestlé) or 'Lactolac V' (Co-operatieve Condensfabriek Friesland, Holland) was used. If no reaction occurred after an initial feeding of 5 ml, the volume was doubled hourly for the first 4 hours and subsequently 3-hourly until daily fluid requirements were met.

---

* < 0.07% Lactose after reconstitution.

Testing of stools
If diarrhoea occurred stools were tested for reducing sugar.

Pathogens
In all infants attempts were made to isolate parasitic, bacterial, and viral pathogens from the stools by culture and by examining stools under the light and electron microscope 12 to 24 hours before and 12 to 24 hours after milk challenge.

Jejunal biopsy
A proximal jejunal biopsy specimen taken with the Watson paediatric capsule just distal to the duodenojejunal junction was examined under dissecting microscope. The specimen was divided into three—one portion was fixed in gluteraldehyde for light and electron microscope studies, the 2nd was used for oligosaccharide enzyme determinations, and the 3rd for immunofluoresence studies. In addition a mucosal imprint was performed to detect *G. lamblia* (Kamath and Murugasu, 1974). Jejunal biopsies were performed (a) prechallenge, immediately before CMP challenge, and (b) postchallenge, 24 hours after the introduction of cows' milk, irrespective of the presence or absence of symptoms. Biopsies were graded by a method described previously (Iyngkaran *et al.*, 1978b).

Assay of intestinal disaccharidases. Portions of jejunal biopsy material were homogenised and incubated with the various disaccharidase substrates as described by Dahlquist (1968). Aliquots of the incubation were assayed for glucose at timed intervals for up to 2 hours using a Glucose Analyzer (Beckman Instruments Inc., Calif. 92634, USA). Disaccharidase activities are reported as µmol of disaccharide hydrolysed/min at 37°C per gram wet weight of tissue.

In 4 infants protein (micro-Kjeldahl method for total protein, Bauer *et al.*, 1974) and enzyme estimations were performed simultaneously. The enzyme levels in these 4 infants were expressed both as per gram wet weight of tissue and per gram protein. The percentage drop in the enzyme levels after milk provocation by either method was almost identical. In the other 19 cases the enzyme levels were expressed as per gram wet weight of tissue.

Results

Initial assessment. The 23 infants comprised 5 Malays, 11 Chinese, and 7 Indians (13 boys and 10 girls). The mean age at admission was 70 days (3–300). The mean duration of diarrhoea was 3·6 days (1–12). Dehydration was present in 13 infants, abdominal distension in 7, anal excoriation in 8, and oral thrush in 7. Interestingly, 8 infants had neonatal jaundice and 5 developed diarrhoea while on phototherapy in a ward with noninfectious patients.

At initial admission stools were positive for sugar in 13 infants; in the other 10, stools were not tested (Table 2). Food poisoning *Salmonella* was isolated from the stools of 4 infants, *Escherichia coli* from 2, and *Shigella* from one.

Assessment at milk challenge. At the time of readmission for milk challenge all the infants were clinically well and registered satisfactory weight gains: 3 were still excreting *Salmonella* and 4 were extreting *E. coli.* These organisms could not have been introduced during challenge studies as stools collected immediately before and after challenge were positive for the same organisms.

Biopsy findings (histological and enzymological). The prechallenge biopsy was normal in 17 infants and mildly abnormal in 6. The infants could be categorised into 4 groups according to the clinical and histological response to CMP after challenge.

Group A. Infants with histological and clinical relapse, symptoms appearing within 24 hours (8 infants)
There was significant depression in the levels of all 3 disaccharidases. In 6 infants with diarrhoea, stools were tested and found to be positive for reducing sugar.

Group B. Infants with histological and clinical relapse but symptoms appearing at 3 and 14 days after milk provocation (2 infants)
There was significant enzyme depression in both infants.

Exclusion of CMP produced prompt cessation of symptoms in infants of groups A and B.

Group C. Histological relapse but no clinical symptoms (8 infants)
Disaccharidase levels were depressed in 7 of the 8 infants. Two have been lost to follow-up. The remaining 6 were thriving well on a CMP formula, when last seen 1 to 24 months after milk provocation but, in 2, initial weight gains were suboptimal.

Group D. No histological or clinical relapse (5 infants)
Although some variability in the pre- and postchallenge enzyme values were observed, there was no consistent fall in enzyme levels as in the 17 patients in groups A, B, and C.

Although the reduction in the mean levels of the disaccharidases in group A was significantly greater than those in group C the levels in individual cases overlapped greatly.

The clinical features, Clinitest results, stool isolates, histological findings, and enzyme values in the 4 groups are summarised in Tables 1 to 5.

Discussion

Secondary sugar intolerance complicating AIE in young infants appears to be due to depletion of the disaccharidases secondary to mucosal damage caused by the primary infective agent (Lifshitz *et al.*, 1971; Barnes and Townley, 1973). In the management of such infants the sugar is identified and excluded from the diet. Dietary manipulation becomes more difficult in those infants who do not improve with this simple approach. It often culminates in some being placed on an oral carbohydrate-free formula (Sirolac, CF1, Nestlé), with glucose given intraveneously (Lifshitz *et al.*, 1970; Walker-Smith, *et al.*, 1973). However, a certain proportion of these infants continue to have diarrhoea despite the total exclusion of carbohydrate from the oral feeds. Harrison *et al.* (1976) suggested a possible association between CMPSE, lactose intolerance, and AIE. Recently, studies in young infants with AIE showed that the feeding of CMP during recovery damages the small bowel mucosa (Iyngkaran *et al.*, 1978a). Such damage could in itself perpetuate the diarrhoea or, by depleting the mucosal disaccharidases, contribute to the problem of secondary sugar intolerance.

18 of 23 infants with AIE in the present series had CMPSE by the criteria of Iyngkaran *et al.* (1978b). In 17 of these infants significant depression of the disaccharidases occurred after provocation with CMP. 10 of these infants had diarrhoea, 8 within 24 hours and 2, on days 3 and 14, after milk provocation. Stools were positive for reducing sugars in 6 infants. As the CMP formulae used in the provocation studies were glucose based and had negligible amounts of lactose, it is suggested that CMP not only impairs digestion and absorption of disaccharides but also of monosaccharides.

Table 5 *Disaccharidase levels, mean (and range)* in 23 infants with acute enteritis before and after cows' milk provocation*

Group	*No. of cases*	*Disaccharidase*	*Prechallenge*	*Postchallenge*	*Percentage change‡*
A	8	Lactase	3·3 (0·7–5·8)	0·5 (0·1–1·4)	85 (76–97)

D	5	Lactase	2·3 (1·4–3·4)	2·4 (1·4–4·1)	−4·0 (−20 to 0)
		Sucrase	3·0 (1·4–5·1)	2·9 (1·7–4·1)	2·0 (−20 to 20)
		Maltase	12·1 (7·7–17·3)	13·1 (7·9–17·1)	−2·5 (−20 to 12)

*µmol/min per g wet weight tissue.

†Included in this group is one infant who had histological changes without significant alterations in any of the disaccharidases.

‡Percentage change $= \frac{(\text{prechallenge} - \text{postchallenge})}{\text{Prechallenge}} \times 100$; positive values indicate decrease and negative values increase over the prechallenge.

Not all 17 infants with histological changes and enzyme depression developed symptoms. Similar observations have been made in coeliac disease (MacDonald *et al.*, 1965). The severity and extent of damage, the amount of lactose, the amount and type of CMP in the diet, the ability of the infants to digest the protein and render it harmless, their ability to mount an appropriate immunological reaction, and the presence of intercurrent enteric infections are some factors that may determine whether or not symptoms manifest in them.

The immunological mechanisms for the exclusion of foreign protein such as CMP by the intestinal mucosa are age dependent (Taylor *et al.*, 1973; Walker, 1975). In young infants this problem may become exaggerated in any situation such as AIE where damage to the intestinal mucosa further increases the permeability to foreign protein. The free passage of foreign antigen across the mucosa could then sensitise the intestinal mucosa to the protein. Subsequent re-exposure to the protein could then result in an immunological reaction at the mucosal level; this may lead to secondary damage of the small bowel mucosa and the attendant consequences of diarrhoea, secondary sugar intolerance, malabsorption, and failure to thrive (Harrison *et al.*, 1976; Iyngkaran *et al.*, 1978a). Therefore in the management of young infants with sugar intolerance secondary to AIE, a lactose- and CMP-free formula should be used and continued for some weeks after recovery.

The deleterious effects of CMP in infants with AIE and secondary sugar intolerance have gone unrecognised in the past because most of the lactose-free milk preparations such as Sobee, Prosobee, Nutramigen, and Pregestimil (Mead Johnson) are also free of CMP. Clearly more studies are needed to confirm these findings and the magnitude of the problem. This would then pave the way for a review of some of the current concepts of secondary sugar intolerance complicating AIE and enable the formulation of a more rational approach to treatment.

We thank P. Thirukumar and S. Arichandran for technical assistance and Sister Tang, Azizah, and the nursing staff for co-operation. This project was supported by funds from the Research Committee of the University of Malaya and in part by Bristol Myers (Research Division), New York, USA.

Prognostic factors in acute meningococcaemia

L. S. LEWIS

Department of Paediatrics, Ahmadu Bello University Hospital, Zaria, Nigeria

SUMMARY During a meningococcal (group A) epidemic, 47 Nigerian children with acute meningococcaemia without meningitis were studied. Their mortality rate was 43% compared with 8% during the whole epidemic. Those presenting with coma and shock had a mortality of 93%, but without shock or coma mortality was only 6%. Coma or shock occurring alone carried an intermediate prognosis. The outcome correlated with initial serum antigen titre, but not with the serum levels of endotoxin, cortisol, or fibrin degradation products. Chloramphenicol was as effective as penicillin. A predictor of expected mortality, based on serum antigen titre and the presence of coma or shock, may allow new forms of treatment to be assessed.

Acute meningococcaemia still has a high mortality during African epidemics (Lapeyssonie, 1963), as in the rest of the world, especially in those patients without meningitis. Mortality rates in such patients were as high as 60% with Flexner's intrathecal antiserum therapy during the 1930s. Subsequent use of antibiotics, corticosteroids (May, 1960), heparin (Niklasson, *et al.*, 1972), digoxin, and IV fluid regimens (Murray *et al.*, 1974; Cahalane and Waters, 1975) has not lowered the mortality. Edwards (1971) showed that high titres of meningococcal capsular antigen are found in the serum during the fulminant form of the infection, and suggested that a threshold level, beyond which disease is irreversible, might exist. The value of other prognostic indices —such as hypotension, duration of purpura, CSF counts, and peripheral blood counts—has been discussed (Stiehm and Damrosch, 1966; Niklasson *et al.*, 1971). We studied some of these factors and also serum levels of endotoxin and cortisol, and fibrin degradation products (FDP) in an homogenous group of Nigerian children suffering from acute group A meningococcaemia, during a large short-lived outbreak. A report on the general features of the epidemic, with its overall mortality of 8%, is in preparation.

Patients and methods

Patients. 47 children with acute fevers, petechial haemorrhages, and CSFs clear to the naked eye were chosen from a total of 530 paediatric admissions for meningococcal disease. During the 3-month epidemic, this group served to define clinically a syndrome of 'acute meningococcaemia without meningitis'. Diagnosis was proved in 37 either by the detection of group A antigen by countercurrent immunoelectrophoresis (Edwards, 1971), or by a positive culture from blood or CSF. Two of the 10 unproved cases died before they could be investigated. Four others had siblings with proved meningococcal meningitis, and the remaining 4 lived close to known cases.

Age ranged from 1½ to 12 years (mean 5·9) and 26 (55%) were boys. The highest CSF WBC was $250/\text{mm}^3$ ($0\cdot250\times10^9/\text{l}$) and 80% of patients had counts lower than $5/\text{mm}^3$ ($0\cdot005\times10^9/\text{l}$).

In most patients continuous monitoring of BP, central venous pressures (CVPs), ECGs, and rectal and skin temperatures was maintained.

Treatment. Either benzylpenicillin (1 megaunit 6-hourly IV if patient under 4 years, up to 3 megaunits 6-hourly if over 8 years), or chloramphenicol (25 mg/kg 6-hourly IV) was given.

In any patient with shock (defined as systolic BP <3rd centile for an American population, i.e. <75 mmHg under 4 years, and <85 mmHg over 4 years), IV dextran 70 was given as quickly as possible until CVP and BP were restored.

At first digoxin was given to patients with pulmonary oedema, but later in the epidemic, this treatment was given to all hypotensive patients.

Prednisolone (50 mg 6-hourly IV) was given to some patients late in the epidemic.

Laboratory methods. Studies were performed on encoded specimens of serum and CSF taken at

---

Ninewells Hospital, Dundee, Angus
L. S. LEWIS, medical registrar

presentation. Endotoxin assay was used for samples collected in endotoxin-free bottles (after swabbing the skin with iodine) and preserved deep-frozen. With the Limulus test and chloroform-extraction (Levin *et al.*, 1972), the lysate used (Marine Biologicals) could detect a standard endotoxin diluted in serum at a level of 2 ng/ml. A semiquantitative assay of FDP was performed by the slide latex agglutination test (Burroughs-Wellcome). Serum cortisol was assayed by competitive protein-binding (Murphy *et al.*, 1963).

Because of local mores, there were no necropsies.

Statistics. Unproved cases are not included in the results. Nonparametric tests were used if appropriate, and methods are quoted in each case.

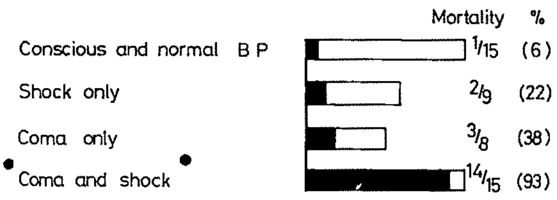
Results

Mortality. 20 of the 47 clinically diagnosed cases died. Of the 37 proved cases, 18 (49%) died. All survivors were completely cured. Most (55%) deaths occurred in the first 4 hours in hospital, and 80% during the first 12 hours.

Clinical presentation and prognosis. Of the various presenting features, shock and coma (absence of co-ordinated response to pain) were the most decisive prognostically (Fig. 1). If a child presented with a normal BP and was conscious his chances of recovery were good. Nearly all children presenting with both coma and shock died. Shock or coma carried an intermediate risk.

Length of history did not correlate with mortality: 80% had been ill for <24 hours, and 40% for <12 hours. The proportion dying in each group was the same.

All 47 children had conjunctival petechiae easily seen, and 20 had purpura less obvious on their dark skin. Those with skin purpura had a higher mortality than those without (50% compared with 37%), but this was not statistically significant.



(Solid areas indicate deaths; $P<0{\cdot}001$ $\chi^2=24$)

Fig. 1 *Mortality and presenting syndrome.*

The height of fever did not relate to mortality, but a rectal temperature exceeding skin temperature by 3°C or more (reflecting the vasoconstricting shock) did.

Clinical progress. Some patients, although initially well, deteriorated during the first 8 hours of observation, while others made a progressive recovery (this difference was shown to relate to serum antigen titre). The mode of deterioration was characteristic; rate and depth of respiration increased, conscious level fell, and purpura extended as CVP fell to zero. Heart rate rose to over 150/min as BP fell, often suddenly and to unrecordably low levels. Although BP and CVP rose with dextran, the coma and hyperventilation usually persisted, with tetany and features strongly suggesting pulmonary oedema (widespread rales and copious frothy blood-tinged sputum). The CVP, usually held below 10 cm, never exceeded 14 cm, while ECG showed sinus tachycardia (150–180/min), S–T segment changes (usually digitalis effect), and an unchanging normal axis. Arrythmia was rare: in one patient a few ventricular ectopics were seen and, in one other, a wandering pacemaker. Bleeding from mucosae or venepuncture sites occurred in only the comatose and deeply shocked patients, all of whom had received dextran.

Treatment. Penicillin and chloramphenicol were equally effective. In patients in whom the diagnosis was proved, 7 out of 14 given chloramphenicol and 11 out of 22 given penicillin died. The two groups were evenly matched for age, presenting features, and serum antigen titre.

Dextran 70 was almost always effective in restoring CVP and BP; usually 20 ml/kg was required. In the absence of controls, a reduction in mortality cannot be shown.

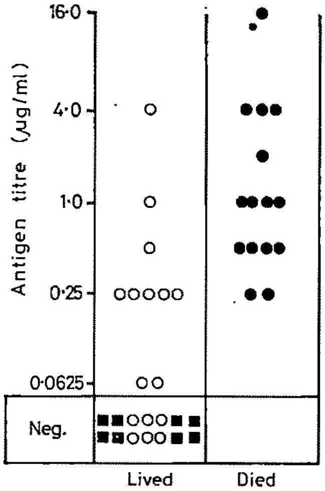
Digoxin had no discernible effect clinically, but ECG showed S–T effect without obvious toxicity.

Prednisolone, given to only 6 patients, had no apparent effect. Phenoxybenzamine was given to 2 patients in unresponsive shock. One died after an hour: in the other, despite rapid resolution of shock and pulmonary oedema, coma persisted until death 4 weeks later.

Laboratory findings.

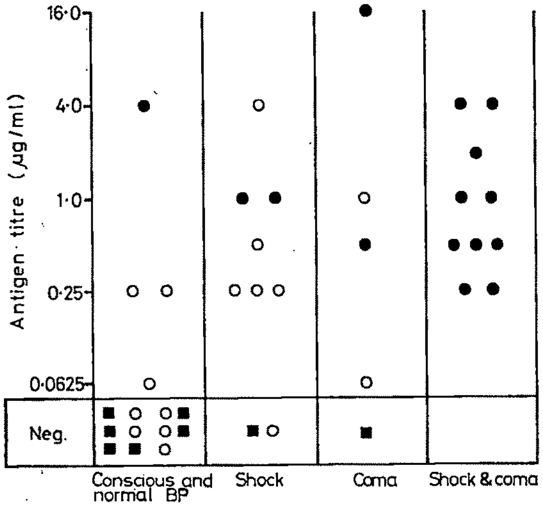
Serum antigen

The presence of group A antigen in serum correlated with mortality; 17 (57%) out of 30 antigen-positive cases died while none of the 6 antigen-negative (but proved) cases died ($P<0{\cdot}025$ Fisher's exact test). The titre of antigen also correlated with mortality (Fig. 2; $P<0{\cdot}001$ Mann-Whitney test).



■ = Not bacteriologically proved.

Fig. 2 *Mortality and serum antigen titre.*



○ = Lived, ● = died, ■ not bacteriologically proved.

Fig. 3 *Mortality, presenting syndrome, and antigen.*

All patients with an antigen titre $<0·25$ μg/ml survived, but there was no threshold beyond which death was inevitable. If serum antigen titres are compared with the presenting features (Fig. 3), it is obvious that higher titres relate to more severe disease ($P<0·025$ Kruskall-Wallis test).

Endotoxin

Assays on sera of 7 healthy controls gave one positive result (i.e. >2 ng/ml). Six out of 16 patients' sera had positive results. There was no relation between a positive result and either clinical severity or mortality. Death occurred in one out of 6 children with a positive result, and in 2 out of 10 with a negative one.

Fibrin degradation products

Initial serum titres showed no correlation with clinical severity, bleeding complications, or mortality. Three out of 7 patients with FDP <10 μg/ml died as did one out of 3 with a level >40 μg/ml.

Serum cortisol

Levels are shown in Fig. 4. All are high (normal range 100–500 nmol/l; 3·6–18 μg/100 ml) with no significant difference in mean level between those who lived (708±SD 109) and those who died (724±SD 273). The levels did not correlate with clinical syndrome, antigen titre, FDP, or endotoxin levels.

Cerebrospinal fluid

Antigen was detected in 8 patients' CSF, 4 of whom had cell counts below $5/mm^3$ ($0·005\times10^9/l$). CSF culture was positive in 10 patients, 3 of whom had cell counts lower than $5/mm^3$. CSF endotoxin assay was positive in 5 out of 15 patients. None of these findings related to clinical features, serum findings, or mortality.

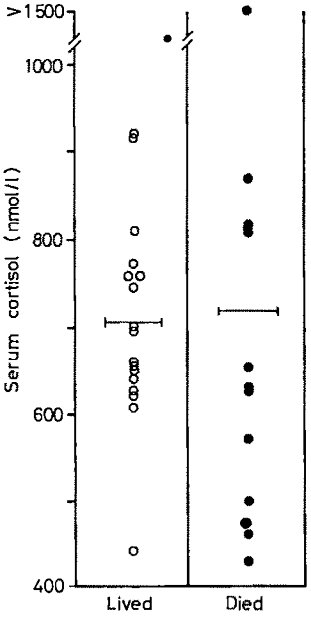


Fig. 4 *Mortality and serum cortisol.*

Discussion

The identification of poor-risk meningococcaemic patients on the clinical findings of petechiae, fever, and clear CSF is imperative during epidemics. Diagnosis may quickly be confirmed by finding group A specific antigen in the blood, and bedside prognostication is improved by antigen titration. Ideas on the mechanism and management of the ensuing catastrophe continually change, so the important facets are considered in the light of our findings.

Banks (1948) described 4 forms of acute meningococcaemia: the ordinary, the 'adrenal', the encephalitic, and the 'mixed' form, corresponding to our clinical categories. His stress on brain injury, supported by necropsy findings, has received too little attention in other studies. This was a crucial prognostic factor in our patients, and was evident as coma regardless of BP, pulmonary oedema without a raised CVP, and tetanic hyperventilation. It was not related to meningitis in the sense of a cell exudate, although in some patients a positive culture or antigen was found in an acellular CSF—a long-known fact (Glasscock, 1935). The shock itself may be of central nervous origin (Ducker and Simmons, 1968), mediated by pulmonary (Udhoji *et al.*, 1963) or splanchnic (May, 1960) pooling, rather than by cardiotoxicity (Levin and Painter, 1966; Hardman and Earle, 1969). Hypotension is preceded by hyperventilation, failing consciousness, and a fall in venous return without actual change in blood volume (May, 1960). The full-blown syndrome with frank pulmonary oedema was seen in several patients at presentation, and therefore cannot be attributed to excessive IV infusion. In our patients digitalisation was of doubtful benefit, but dextran restored BP and CVP. Although α-blockers and β-stimulants hold promise for correcting the circulatory changes, in our 2 patients so treated coma persisted until death. There was no evidence that the encephalitis responded to corticosteroids, but its reversal in 6 patients not given corticosteroids was encouraging. 'Suprarenal apoplexy' (Waterhouse, 1911) is an unlikely cause of death as shown by the high cortisol levels, clinical findings, and ineffectiveness of corticosteroid treatment.

Endotoxaemia as detected in our patients was also of no prognostic significance; perhaps the Limulus test lacks clinical value (Stumacher *et al.*, 1973), or endotoxin is not the central issue after all (Kass *et al.*, 1973).

Disseminated intravascular coagulation (DIC), although clearly demonstrated in acute meningococcaemia, may likewise be unimportant or perhaps it is unresponsive to heparin. Initial FDP level did not predict progress. Of 70 heparin-treated cases in 15 reports (Niklasson *et al.*, 1972) 38 patients died. A controlled trial of heparin (Manios *et al.*, 1971) did not show significant benefit. The dextran used in our patients may have countered DIC and improved microcirculation, but it was intended primarily as a plasma expander.

High serum antigen levels at presentation, while not invariably fatal, point strongly to a poor prognosis. This free antigen may be a quantitative marker of live organisms, their dead products, or of an ineffective immune neutralisation and/or phagocytosis. In meningococcal meningitis, CSF antigen level has been correlated with brain damage and higher mortality, and serum antigen positivity with higher mortality (Whittle *et al.*, 1976). Further study to define the role of antigen is needed.

Long experience of sulphonamides (May, 1960) and penicillin, and the effectiveness of chloramphenicol in our patients, suggest that the choice between a bactericidal or bacteriostatic drug is immaterial, provided that the organism is sensitive. It seems that fulminant meningococcaemia is caused by unlimited multiplication of unneutralised bacteria which disrupt leucocytes, and activate the complement (Greenwood *et al.*, 1976) and coagulation pathways; perhaps crucially they have direct toxic effects (although possibly not endotoxic) on the brain. Fulminant disease is present in only a small proportion of the population during meningococcal epidemics. The susceptible may have low levels of circulating antimeningococcal antibody (Goldschneider *et al.*, 1969), or a defect of antibody response (Whittle *et al.*, 1976), although polymorph dysfunction cannot be ruled out. Since a few dramatic recoveries have been reported using IV antibacterial (Glasscock, 1935) or antitoxic sera (Hoyne, 1935), and modern treatment persistently fails to reduce mortality, we intend to try the combination of IV penicillin and IV antiserum in severe cases. A simple prognostic index, based on the presenting features of coma, shock, and serum antigen level should help to assess such treatment.

I wish to thank Drs H. C. Whittle and B. M. Greenwood for their help and guidance; Professors R. H. Dobbs and M. K. Haggie, the staff and students of the paediatric department: Mr M. Damisah for his expert laboratory work; Professor I. D. P. Wootton, Dr K. Mashiter, and Miss S. Baker of the Royal Postgraduate Medical School for the cortisol assay.

Addendum

Since submitting this paper, we have found highly significant depressions of serum antithrombin III levels correlated with prognosis; this may help to explain the apparent unresponsiveness of the condition to heparin.

Aortic arch interruption presenting with absence of all limb pulses

G. P. SHARRATT, R. LEANAGE, J. L. MONRO, AND E. A. SHINEBOURNE

Wessex Regional Cardiothoracic Centre, Southampton, and Brompton Hospital, London

SUMMARY Three patients with aortic arch anomalies presented with severe heart failure, acidaemia, and poor or absent upper and lower limb pulses. Prominent carotid arterial pulsations were detected which distinguished the condition clinically from aortic atresia. In 2 patients with a left aortic arch, interruption was distal to the left common carotid artery and there was an aberrant right subclavian. In the 3rd patient with a right aortic arch, interruption was distal to the right common carotid and there was an aberrant left subclavian artery. By dilating the narrowed ductus, prostaglandin E2 infusion corrected the acidosis. Successful surgical correction was achieved in one patient by direct anastomosis of descending aorta to ascending aorta and the base of the left common carotid artery.

Complete interruption of the aortic arch is a rare congenital anomaly which normally presents in infancy with heart failure and acidaemia (Fishman *et al.*, 1976). There is almost always a ventricular septal defect and persistence of the ductus arteriosus (Roberts *et al.*, 1962). When the interruption is between the left common carotid artery and the left subclavian artery (type B of Celoria and Patton (1959)), the descending aorta is supplied from the pulmonary artery via the ductus arteriosus and also by retrograde flow from the left vertebral artery, which also supplies the left subclavian artery.

When an infant presents with cyanotic congenital heart disease, heart failure, acidaemia, and reduced or absent upper and lower limb pulses the diagnosis of aortic atresia is likely. With type B interruption of the aortic arch, when the right subclavian artery arises aberrantly from the descending aorta, and the ductus arteriosus constricts (Fig. 1), a similar clinical picture is found. In this case, however, there will be normal or bounding carotid pulses. This is now a surgically correctable lesion and hence the importance of its recognition. We report 2 cases that presented in this manner, and a further similar patient with a right-sided aorta, grossly hypoplastic arch distal to the right common carotid, and aberrant left subclavian artery.

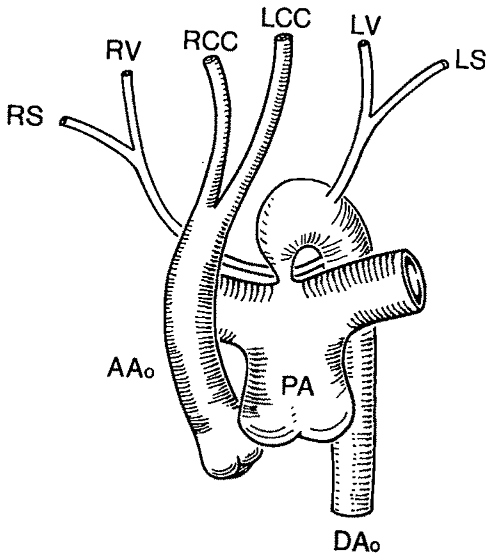

Fig. 1 *The ascending aorta (AAo) gives off only the right common carotid artery (RCC) and the left common carotid artery (LCC). The pulmonary artery (PA) connects with the descending aorta (DAo) through a constricted ductus arteriosus. The left subclavian (LS) and right subclavian (RS) arteries arise from the descending aorta and give off the right vertebral (RV) and left vertebral (LV) arteries.*

Case reports

Case 1. A Caucasian baby boy, normal delivery, born at 39 weeks' gestation with a birthweight of

2·9 kg. On day 2 a murmur was noted and at that time all the peripheral pulses were normal. The next day he became cyanosed, tachypnoeic, and was found to be in heart failure with no pulses palpable in the arms or legs.

He was transferred to the Wessex Cardiothoracic Centre where he was found to be severely tachypnoeic, sweating profusely, with 3 cm hepatomegaly. There were no pulses palpable in the limbs but bounding carotid pulses were present bilaterally. There was a much increased parasternal impulse and on auscultation there was an ejection click, soft short ejection systolic murmur, and a single second sound. The ECG suggested right ventricular hypertrophy and the left ventricular potentials were well seen. The chest *x*-ray showed a large heart with plethoric lung fields.

The echocardiogram showed the presence of 2 atrioventricular valves, 2 ventricles and 2 arterial valves, the anterior of which had midsystolic closure suggesting that it was the pulmonary valve.

Cardiac catheterisation proved the diagnosis of complete interruption of the aortic arch between the left common carotid artery and the left subclavian artery with the right subclavian artery arising aberrantly from the descending aorta (Fig. 1). Injection into the ascending aorta showed delayed retrograde filling of both vertebral arteries, and hence both subclavian arteries and the descending aorta. There was also a ventricular septal defect and a persistent ductus arteriosus. When the catheter was passed from the pulmonary artery to the descending aorta there was loss of pressure waveform and injection of contrast showed very slow clearing from the descending aorta. There was also a small left-to-right shunt at atrial level which proved to be due to a secundum atrial septal defect.

Surgical correction was performed the same day using profound hypothermia, and total circulatory arrest at 18°C (Barratt-Boyes *et al.*, 1971). The technique was virtually the same as that used by Trusler and Izukawa (1975). The descending aorta was dissected and mobilised and the duct divided from the pulmonary artery. The descending aorta, with most of the duct tissue removed, was then anastomosed to the ascending aorta and base of left common carotid artery. The pulmonary arteriotomy was closed and the right atrium incised. The atrial septal defect was closed directly, and the ventricular septal defect was closed through the tricuspid valve using a dacron patch. Total circulatory arrest lasted 68 min and the baby was taken off the ventilator and extubated 6 hours postoperatively. The postoperative course was complicated by intermittent collapse of the right upper lobe, but he left hospital 16 days after the operation.

He has not yet been reinvestigated but was well and thriving 3 months after surgery although he appears to have developed some aortic narrowing as the right arm and leg pulses are absent; however the left arm pulse is still present, but reduced.

Case 2. A Caucasian baby girl, normal delivery, born at 41 weeks. At 36 hours severe tachypnoea and cyanosis was noted and the baby was transferred to Brompton Hospital. On examination the child was extremely sick with absent limb pulses. Bounding temporal and carotid pulses were noted. Respiratory rate was 90/min. Examination revealed a split second sound with a loud pulmonary component and a grade 3/6 pan systolic murmur at the lower left sternal edge. Arterial P_{O_2} in 100% oxygen in the right radial artery was 17·3 kPa (130 mmHg), [H^+] 64 nmol/l (pH 7·19), base excess 19 mmol/l. Cardiac catheterisation showed a left-to-right shunt at ventricular level, equal ventricular pressures, and a pulmonary artery pressure of 52/27 mmHg. The catheter was advanced to the descending aorta where the systolic pressure was 15 mm lower, indicating constriction of the ductus. Left ventricular cineangiography showed a single high ventricular septal defect, filling of the ascending aorta and both common carotid arteries, but no opacification of the subclavian arteries or descending aorta (Fig. 2).

Injection into the left-sided descending aorta showed the left subclavian artery, the aberrant right subclavian, and the constricting ductus arteriosus (Fig. 3). Attempts at surgical correction were unsuccessful: the child died on the operating table.

The necropsy showed situs solitus, concordant atrioventricular and concordant ventriculo-arterial connections. The left-sided ascending aorta was a small channel giving rise only to right and left carotid arteries, confirming the angiographic diagnosis. The pulmonary artery was in continuity through a ductus with the descending aorta, from which arose the left and then right subclavian arteries. The right subclavian artery was posterior ascending behind the oesophagus. The arch was absent between left common carotid and ductus. The large ventricular septal defect resulted from backward displacement of the parietal insertion of the infundibular septum. The displaced infundibular septum caused severe narrowing of the left ventricular outflow tract, i.e. subvalvar aortic stenosis.

Case 3. A Caucasian baby boy, normal delivery, born at 40 weeks. At 24 hours severe tachypnoea and cyanosis was noted and the baby was admitted to the Brompton Hospital at 48 hours. The respiratory rate was 80/min. All limb pulses were barely palpable although temporal and carotid pulsations

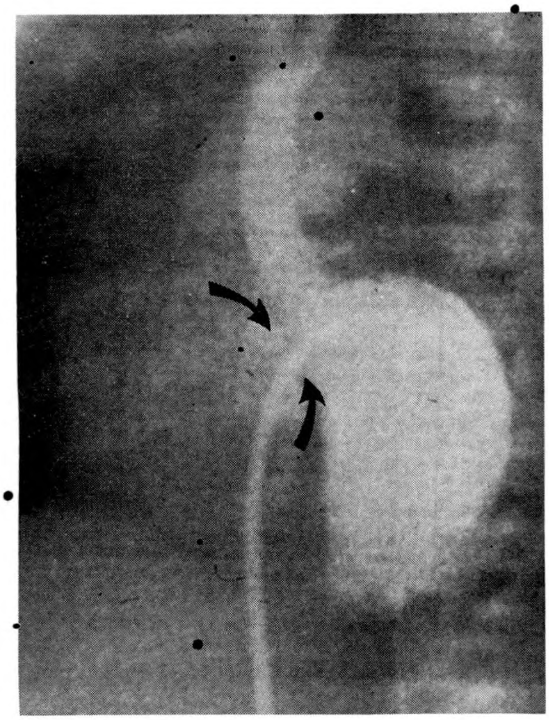

Fig. 2 *Left ventricular angiogram, lateral projection. The ascending aorta arises from the left ventricle and gives off the right and left common carotid arteries. The catheter is across the ventricular septal defect (between arrows) and there is faint left-to-right shunting of contrast across the ventricular septal defect.*

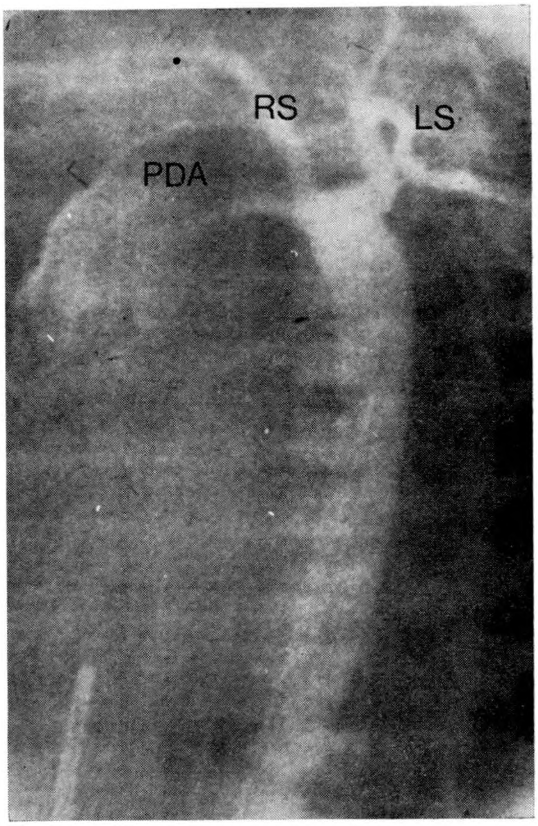

Fig. 3 *Injection of contrast into the descending aorta, lateral projection. The left subclavian (LS) and right subclavian (RS) arteries arise from it and the narrowed ductus arteriosus (PDA) fills.*

were felt. On asucultation there was a split second sound with a loud pulmonary component and a short systolic murmur at the lower left sternal edge. Arterial Po_2 in 100% oxygen was 8 kPa (60 mmHg), $[H^+]$ 64 nmol/l (pH 7·19), base excess 18 mmol/l. The ECG showed left ventricular hypertrophy with deeply inverted T-waves in the left chest leads.

Cardiac catheterisation showed a left-to-right shunt at ventricular level with equal ventricular pressures. The catheter was advanced through the ductus arteriosus into the descending aorta where the systolic pressure was 35 mm lower, indicating ductal constriction.

During and after cardiac catheterisation, acidosis became increasingly severe despite administration of IV bicarbonate. The child was considered too ill to undertake surgery at this stage. In order to improve systemic perfusion which was largely dependent on patency of the ductus, prostaglandin E2 infusion at the rate of 0·10 μg/kg per min was begun. This was delivered directly into the ductus from a catheter inserted via the umbilical artery. Within 15 min peripheral pulses became palpable and acidosis improved. The child remained anuric, however, and died on the operating table.

Necropsy showed situs solitus, normal connections, right-sided ascending aorta giving rise to both right and left common carotid arteries. The pulmonary artery was in continuity through a large ductus with a right-sided descending aorta from which arose the right and aberrant left subclavian arteries. The arch was grossly hypoplastic between the right common carotid and ductus. There was a large defect between the right ventricular infundibulum and the left ventricular outflow tract which appeared to be due to a complete absence of the infundibular septum.

Discussion

Patients with interruption of the aortic arch associated with a ventricular septal defect and persistent ductus arteriosus commonly present with heart failure in the first few days of life and 80% die in the first month. Therefore early recognition of the lesion is vital as surgical correction is possible (Tyson *et al.*, 1970; Barratt-Boyes *et al.*, 1972; Murphy *et al.*, 1973; Losman *et al.*, 1974; Trusler and Izukawa, 1975; Fishman *et al.*, 1976; Ventemiglia *et al.*, 1976; Monro *et al.*, 1977). Origin of the right subclavian artery from the descending aorta has been reported with interruption of a left aortic arch (Evans, 1933; Kleinermann *et al.*, 1958; Tabakin and Hanson, 1960, Zetterqvist, 1967; Morgan *et al.*, 1970; Van Praagh *et al.*, 1971; Subramanian, 1972; Kauff *et al.*, 1973; Murphy *et al.*, 1973; Trusler and Izukawa, 1975). We have been unable to find reports of an aberrant left subclavian artery associated with a hypoplastic right aortic arch.

At necropsy in infants with arch interruption the ductus arteriosus is usually widely patent with some wrinkling of the intima. Fournier and Zaidi (1960), Van Praagh *et al.* (1971), and Subramanian (1972) reported cases in which there had been significant narrowing of the ductus arteriosus. The combination of a right subclavian artery arising from the descending aorta and narrowing of the ductus arteriosus was present in the cases reported by Van Praagh *et al.* (1971), Subramanian (1972), and in 2 of our cases. In these, and in our 3rd case, a characteristic clinical picture of absent or markedly reduced limb pulses with bounding carotid artery pulsation was produced. This occurred because the subclavian arteries arose from the descending aorta, supplied by the narrowed ductus and by retrograde flow in the vertebral arteries. The detection of the large amplitude pulsation in the carotid arteries should suggest the clinical diagnosis. If carotid pulsation is not detected in an infant with heart failure, acidaemia, and absent limb pulses, aortic atresia—an inoperable lesion—may be mistakenly diagnosed. We have seen 2 patients with similar clinical findings caused by an intracranial arteriovenous fistula. The volume overload of the heart, due to the left-to-right intracranial shunt, caused heart failure and all the pulses were small except for the carotid arteries which were bounding as they supplied the arteriovenous fistula.

Infusion of prostaglandin E2 0·1 μg/kg per min has been used to dilate the ductus arteriosus in pulmonary atresia when pulmonary blood flow was dependent on its patency (Rudolph, 1977). Dilatation of the ductus by increasing lower limb flow helped to arrest the progressive acidosis accompanying ductal closure in one case. Aortic arch interruption is a further clinical situation where prostaglandin may be used. Mortality in this condition may thus be reduced as the infants' general condition at the start of surgery should be much improved by the adequate correction of acidosis.

Housing and mothering

Their effects upon the developmental levels of 3-year-old children

MARGARET POLLAK
The Sir Wilfrid Sheldon Assessment Centre, London

SUMMARY The development of 200 3-year-old children was measured, using Gesell parameters of development. The levels of development were matched against the adequacy, or inadequacy, of maternal care and housing, the scales for which were derived from a questionnaire completed by the children's mothers. Housing was not found to affect the children's developmental levels, while the adequacy of maternal care was highly significantly related to satisfactory child development.

Be it castle or city slum, there is no place like home. Does research support this view? It is not easy to differentiate between the facilities of a home and the quality of care therein, and many research studies have failed to make this important distinction. The evidence that is available on the relative importance to a child of his mother and his home is somewhat conflicting. Several studies (Kaufman and Rosenblum, 1969; Spencer-Booth and Hinde, 1971a, b) have shown that monkeys who remained in their own 'homes' were distressed when their mothers were taken away, suggesting that the mother was more important than the home. Ross and Simpson (1971), on the other hand, found no intellectual retardation after the death of a parent if the child remained at home in familiar surroundings. When monkeys and children are removed from their homes they suffer distress (Edelston, 1943; Bakwin, 1949; Mac Keith, 1953; Robertson, 1958), but it is well known that this can be lessened if the mother accompanies the child to the new environment (Prugh *et al.*, 1953; Illingworth and Holt, 1955; Fagin, 1966).

A 'poor' home has been associated with poor educational achievement (Douglas, 1964; Department of Education and Science, 1967), backwardness (Burt, 1937), delinquency (Ferguson, 1966; West and Farrington, 1973), and psychiatric disorder (Rutter, 1976). However, the exact factors in the 'poor' homes which are important for the associations have not been defined.

Few studies have attempted to compare housing and maternal factors with measurable developmental levels in preschool children. But, if it were possible to separate housing conditions from parent care and to compare each of these factors with measured developmental parameters, comments could be made upon the relative importance of them on child development.

Present study

This cross-cultural study was made on 200 3-year-old children. 150 of them were born in the United Kingdom to 75 English parents and 75 West Indian parents. They were all living in the same district of south London, they came from similar social classes, and there were no significant differences in income levels. They have been described in detail elsewhere (Pollak, 1972). The remaining 50 children were living in North Carolina, USA and comprised 25 children born to white American parents and 25 born to negro American parents. These 50 children and their parents were in receipt of 'welfare'.

The 200 children were given 56 different paediatric development tests in their own homes in the presence of their mothers (or permanent mother figure). The tests, derived from Gesell (1954) and recorded (Pollak, 1972), were divided into sections to assess motor, personal-social, adaptive, and language parameters of development. The mothers filled in a questionnaire and from this, a scale of housing and maternal care was made.

Housing scale

1. The house was not multioccupied—i.e. not more than two families lived in the same house. If a flat or apartment, only one family occupied the rooms.
2. The main living room was large enough and had sufficient equipment to enable all the

---

The Sir Wilfrid Sheldon Assessment Centre, London
MARGARET POLLAK, consultant paediatrician

members of the family to sit down to a meal together.

3. The family had its own kitchen with running cold water.
4. The family had its own indoor water closet.
5. There was a usable bathroom for exclusive use of the family.
6. The 3-year-old child slept in his/her own cot or bed.
7. The parents and children had separate bedrooms.
8. Children of different sexes had different bedrooms.
9. There was a garden or play area in which the 3-year-old child could play.
10. The accommodation was self-contained with its own front door. Almost all the children in the USA study were in self-contained houses but they were isolated in lonely rural areas, so their point was scored if the nearest general store was within one mile.

Maternal care scale

1. The 3-year-old child was regularly put to bed by a parent.
2. The child had been given a present or treat for his/her birthday.
3. The mother stated that she spent at least half an hour each day playing with the child.
4. When the child misbehaved he/she was not beaten with a stick or belt, nor had he/she received more than one major punishment during the previous week. (A negative answer to both questions was necessary to qualify for the point.)
5. The mother knew the name of one current television programme for children and watched it with the child at least once a week. (Every household except one had a television set.)
6. During the 1½-hour interview the mother had appeared warm towards the child and had not shouted at him/her.
7. Three toys belonging to any child in the household had been shown to the examiner.
8. The mother was asked an open-ended question to describe her child in 5 different ways according to his/her character and behaviour. Two or more favourable replies scored one point. For example:

   Favourable

   'He's very loving, not selfish, got real good manners'.

   'She's more for her dad, but very loving and sweet'.

   'Oh, he's lovely. Very good most of the time but likes his own way—don't we all?'

   Unfavourable

   'Only gives you trouble. Only good when you belt him'.

   'Everything about him is bad. He just don't give you no mind'.

   'She is very rude. She is stubborn and lazy'.
9. If the mother went out to work she had made appropriate and firm arrangements for the child. In cases where the mother did not work but went out socially without the child, he/she was not left alone in the house or left casually in the charge of another child who was under age 14 years.
10. The child did not have to share his mother's attention with more than two other preschool children.
11. The mother was rated on a 4-point scale by the author for her understanding of and competence in carrying out the needs of the 3-year-old child. Among the factors considered, warmth, hostility towards the child, patience, and teaching skills had high priority.

The total possible score for housing was 10 and, for statistical purposes, a score of 6 or more was considered adequate, while 5 or less was inadequate.

For maternal care, the total possible score was 14. Eight or more was deemed adequate, while 7 or less was inadequate.

Table 1 *56 development tests*

Development	*Top possible score*
Motor	15
Personal-social	10
Adaptive	12
Language	14

The developmental levels of the children in these 4 parameters were then matched against the adequacy or inadequacy of the maternal care and housing scales.

Results

Housing. The development levels of the children were compared with the housing scores. In motor, personal-social, and adaptive development there was no significant difference between the scores when the housing was adequate or inadequate. Only in the case of the West Indian 3-year-old children did inadequate housing significantly lower the development score in language development (Table 2).

Maternal care. A very different picture emerged when the children's developmental levels were compared with the maternal care scales. For all groups of children adaptive, language, and personal-social development were highly significantly related to the adequacy or inadequacy of maternal care. For the West Indian children motor development was also affected. In all cases, inadequate maternal care was related to a lower developmental score (Table 3).

Maternal care versus housing. For the children of this study the quality of maternal care was vital for their levels of development, but the adequacy of housing was not of similar importance (Table 4). Furthermore, the adequacy of maternal care was not found to be synonymous with adequacy of housing. A correlation graph (Figure) shows that the adequate mothers were not necessarily the mothers who were living in adequate housing.

Discussion

It may appear a truism that a child's development is highly significantly related to his mother's love and care but is little affected by the circumstances and amenities of his home. However, this is not necessarily the case. A search in the literature for a study with which to compare these results fails to uncover any in which the various parameters of development are subjected to statistical relevance vis-à-vis maternal care and housing. Deprivation of maternal care has been associated with mental health (Bowlby, 1951), retarded language (Rutter and Mittler, 1972), and IQ (Haywood, 1967), but in no case with several parameters of development and housing factors.

It did not prove easy to devise the maternal care scales since the exact factors which contribute towards 'good' maternal care are not known. The factors which made up this scale were: care and attention (4 questions), warmth (2 questions), stimulation and interaction (4 questions), and the 4-point subjective rating. Because of the difficulty, direct answers given by the mother to direct questions put to her were used whenever possible. It was felt that as the questioner was the family doctor of all the UK mothers and children and was well known to them and the questions were asked close to other factual questions, the replies received were likely to be correct and many could be confirmed by observation.

In addition to the main conclusions of this study, it is possible to comment on some aspects of the different parameters of development. For example, there is some evidence to suggest that the genetic influence on motor development is strong (Illingworth, 1960; Geber and Dean, 1957, 1964; Pollak and Mitchell, 1974) and, because in this study motor development appears to be little influenced either by the housing or maternal care, both of which are environmental factors, the results could lend indirect support to this theory.

On the other hand, some workers who have been concerned with the environmental factors which affect child development have cited language development as an example of development which can be delayed by environmental factors. When opportunity to learn is meagre, language development can show retardation (Luria and Yudkovitch, 1959; Ausubel, 1963; Bernstein, 1965). This study supports this view but shows decisively that maternal care rather than housing is the significant variable. Clinical experience suggests that language development, alone, depends substantially on environmental factors.

Maternal care is found to have a significant effect upon adaptive development. Gesell and Armatruda (1947) have written 'The term adaptive behaviour is therefore a pertinent one to describe the category of

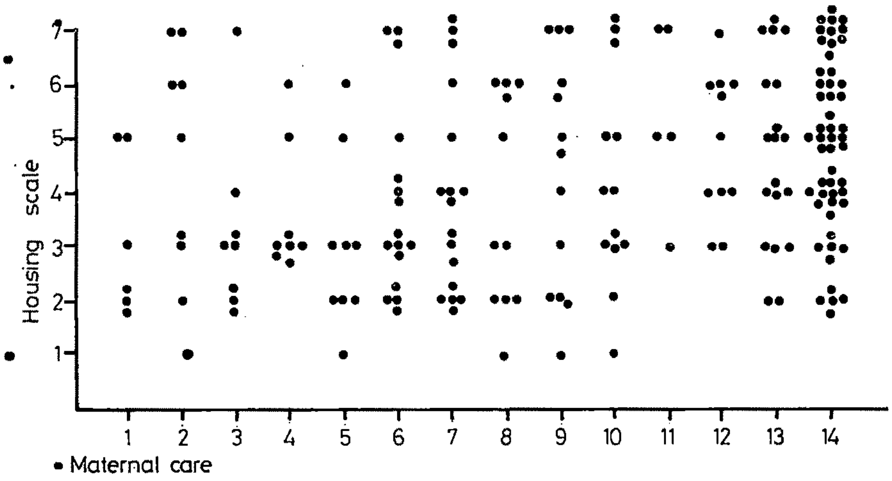

Figure *Housing v. maternal care.*

behaviour in young children which most correlates with what in older children is designated intelligence'. If one accepts this statement, then the results of this study suggest that inadequate mothering may carry a grave prognosis.

This research gives no information on the effect of housing upon mothers. Adequate shelter which contains the basic requirements for satisfactory housekeeping is a necessity for every mother and her family and we do not know whether a lack of these necessities caused depression and frustration in some mothers and thus affected, indirectly, her children. It is also not possible to comment on which factors in the maternal care scale were the most important.

The results of this paper put the onus of satisfactory development of the 3-year old firmly on the lap of maternal care and show that the adage 'There is no place like home' is only likely to be true when it contains an adequate mother.

The Statistical Unit of the Royal College of General Practitioners gave statistical advice and help.

Conservative care of the newborn baby

T. H. HUGHES-DAVIES

Odstock Hospital, Salisbury, Wiltshire

SUMMARY A method of managing ill and premature babies with little disturbance is described. The results of such care during 1969–76 compare favourably with those achieved by more intensive and active intervention.

Small or ill babies dislike being disturbed, and in the mid 1960s it seemed to me that intervention did harm as often as it did good. Here is described a way of leaving babies alone and its results.

Method

1. All babies are nursed prone and head up on an apnoea mattress. In this position the pharynx clears itself, the stomach is self winding, the lower oesophagus is protected by the gastric air bubble, and the brain drains uncongested.

2. The baby is never left naked but is covered at least by a towel napkin to reduce radiant heat loss. At night and on cold days, the nursery curtains are drawn.

3. A nasal tube is passed and feeding and watering begun within half an hour of admission. Feeds are given from outside the incubator without touching the baby. Babies fed only milk cannot satisfy their thirst and hunger independently as older children do. Most cope, but some become obese in an attempt to get enough water, or become oversalted, uraemic, and anorexic from a failure to do so. We therefore follow the example of other mammals by offering water 3 times a day to all babies. Those not sucking get their water down the tube in a volume equal to one of their milk feeds, with an increase if they are hot or uncomfortable. This is usually given as 10% glucose to the smaller babies as prophylaxis against hypoglycaemia, but water would probably be as good and perhaps safer, although we have had no trouble. Human milk expressed or from the breast, is used for the smaller babies and, if available, for the rest; but all milks seem well tolerated with supplementary water. For convenience we used pre-bottled milk when it became available. The quantity is increased from about 60 ml/kg per day on the 1st day to 120 ml/kg on the 3rd, up to 200 ml/kg by the 7th, depending on the state of the baby and the judgement of the sister.

4. At the first suspicion of respiratory difficulty an *x*-ray of the chest is taken, and acidaemia is anticipated and averted by adding sodium bicarbonate to the feed at a rate of $\frac{1}{2}$–1 mmol/h. The carbon dioxide formed leaves by the oesophagus, so the neutralisation is independent of lung function. The head up tilt is increased to 30° in the hope of reducing collapse of apical alveoli during expiration.

5. Blood glucose is checked by Dextrostix, at first every hour; and bilirubin as necessary by heel prick. No venous samples are taken except for culture if an infection is suspected. Nothing is given intravenously, except occasionally during initial resuscitation, or later for the correction of anaemia.

6. A stream of piped air, or air and oxygen, is directed from a funnel at the baby's face as a stimulus against apnoeic attacks. The concentration of oxygen is checked regularly, and enough given to prevent cyanosis.

7. Ventilators and positive pressure devices are not used, nor is phototherapy.

8. Isolation is kept to a minimum, and depends largely on the incubator and on hand washing. The nursery is open to mothers and relatives who are encouraged to help with the babies' care from the start. Masks and overshoes are not used, and gowns only for convenience; gloves are used for passing tubes.

9. During exchange transfusion, the umbilical catheter is sandwiched between two layers of adhesive film covering the abdomen, and the baby lies prone and unfettered in his usual position in the incubator.

Results

In 8 years, 911 babies under 2500 g were born. This was 6·1% of all births, and close to the national

---

Central Hospital, Honiara
T. H. HUGHES-DAVIES, consultant paediatrician

average of 6·3%. Of these, in 1974–76, 48·3% were between 2500 and 2250 g, 20·7% between 2250 and 2000 g, 19·1% between 2000 and 1500 g, 7·9% between 1500 and 1000 g, and 3·9% were under 1000 g. The corresponding figures for England and Wales for 1975 were 48·2, 22·8, 17·9, 7·4, and 3·5% respectively. Any larger baby about whom there was concern was also admitted to the nursery, and about one-third of all babies passed through if only for a few hours.

Hypothermia, hypoglycaemia, enterocolitis, pneumothorax, and bleeding and thrombotic complications were seldom met. Exchange transfusion was needed only for haemolytic disease, and there has been no late evidence of kernicterus. Babies with respiratory distress left undisturbed have done well with no late lung disorder. Apnoea has been severe only in babies later found at post-mortem examination to have cerebral haemorrhage from birth trauma. One severely retarded child is partially sighted and has retinal changes which may be related to ventilation with pure oxygen during half an hour's apnoea at birth; he did not need oxygen subsequently.

After discharge the babies were seen if necessary at a clinic held each week in the nursery, where the mothers were at ease and the nurses could see the results of their care. They did well. The few affected children were not those who had caused concern in the first weeks, and most had evidence of an intrauterine infection or some other handicapping condition. Some who had had unduly prolonged resuscitation at birth, and who needed tube feeding for a long time, remained severely retarded—the 'failed stillbirth' group for whom the answer is perhaps to limit initial ventilation for apnoea to 30 minutes or so, when there is evidence of profound intrapartum anoxia.

Death in the first week is the best defined measure of comparison; the number of deaths and births by weight is shown in Table 1, and the 3-year running average mortality in Table 2. All deaths are included whether they occurred in the delivery room, in the nursery, or after transfer to another hospital for surgery. Included in the table are the deaths in the first month for England and Wales by weight in 1975; and also deaths among 1017 babies of <2500 g admitted to six neighbouring nurseries in 1975, but it is likely that not all the larger babies are included in these figures.

Among the smaller babies there was an initial rise followed by a steady fall in the mortality. As the care of the babies was unchanged, and the fall much steeper than the national trend, these changes are probably due to improvement in obstetric care. This was reflected in a corresponding fall in the number of babies who died after 20 minutes or more of apnoea at birth, or who had tentorial tears at post-mortem examination. Of the lethal deformities 19 were in babies >2500 g and 8 in smaller ones. Table 3 gives the cause of other deaths by year and weight. Table 4 shows the mortality of very small babies of <1000 g. This is high, but little different from that of babies born in University College Hospital, London as derived from the figures of Stewart *et al.* (1977), or from that reported by neighbouring nurseries.

Discussion

Different hospitals serve different populations, and reliable comparison between methods of care is difficult but should be attempted. The results of conservative treatment presented here seem no worse than those of more intensive care; and it may be that the method will be of use to other small hospitals in this country and overseas. The incidental benefits were considerable; nurses and doctors as well as babies got more rest, and it became practicable if not desirable to run the nursery with one trained and one assistant nurse or less per shift, with

medical cover from a single doctor who also had responsibility for all the other paediatric work in the hospital.

It has been suggested that small babies should be transferred to regional centres. Table 4 shows that there has been little change in the mortality of very small babies in successive 5-year periods in one of the best of these; and that when babies of 30 weeks' gestation or more are removed the mortality differs little from the national average. Our experience suggests that improvement in perinatal mortality depends largely on the care of the mother and her baby before and during birth.

I am indebted to Sister Rowlands and the staff of Salisbury special care nursery for their help, and to neighbouring paediatricians for their kindness in providing figures.

Plasma somatomedin activity in protein calorie malnutrition

P. S. MOHAN AND KAMALA S. JAYA RAO

National Institute of Nutrition, Indian Council of Medical Research, Hyderabad

SUMMARY Somatomedin activity was assayed in the plasma of children suffering from protein calorie malnutrition by a bioassay using rat cartilage and expressed as sulphate uptake ratio. The sulphate uptake ratio was particularly reduced in kwashiorkor. In marasmus there was a slight reduction and the levels were still in the normal range. Plasma growth hormone (GH) levels were raised in kwashiorkor but were in the normal range in marasmus. Reduction in sulphate uptake ratio was observed only when plasma albumin levels were less than 2·5 g/100 ml (25 g/l). A rise in plasma GH was also observed but only below this threshold level.

Some of the actions of growth hormone (GH) on cartilage are believed to be mediated through GH-dependent serum factors—the somatomedins (Daughaday, 1971). The liver is one of the known sites of somatomedin generation that has been shown to be stimulated by GH (McConaghey, 1972).

Raised GH levels have been observed in kwashiorkor (Raghuramulu and Jaya Rao, 1974), a condition in which the concentrations of various proteins synthesised in the liver, including albumin, are markedly decreased. A lowered level of serum somatomedin may act as a feedback to stimulate excess production of GH in this condition. Plasma somatomedin is generally measured by bioassays, in which the uptake of either $Na_2{}^{35}SO_4$ or ^3H-thymidine by cartilage in the presence of serum is determined. To test whether any correlation exists between plasma GH levels and somatomedin activity in protein calorie malnutrition, the ability of serum from children suffering from such malnutrition to stimulate $Na_2{}^{35}SO_4$ uptake by rat cartilage was studied.

Patients and methods

Eight children suffering from kwashiorkor and 7 marasmic children were studied. They conformed to descriptions given earlier (Raghuramulu and Jaya Rao, 1974). Investigations were carried out immediately on admission to hospital and after 3 or 4 weeks of nutritional rehabilitation on diets which provided 200 kcal (0·836 MJ) and 4 g protein/kg daily. A sample of venous blood was obtained after an overnight fast, under resting conditions. Blood was collected under heparin, plasma separated, and stored at —20°C.

The bioassay was carried out as described by Yde (1968) using 21–27 day-old male albino rats, fasted for 48 hours before the assay. The cartilage pieces were however not subjected to acid hydrolysis but digested with papain (Alford *et al.*, 1972). The radioactivity in the hydrolysate was measured in a Packard liquid scintillation counter, using Bray's scintillating solution.

The assay was carried out by a symmetrical 4-point bioassay using both reference (pooled plasma from healthy adults) and test plasma at 10% (0·07 ml) and 20% (0·14 ml) of the total incubation volume (0·7 ml). Each concentration of the plasma was assayed in triplicate. Radioactivity was expressed per mg dry weight of the cartilage. The ratio of the radioactivity obtained with the test plasma to that obtained with the reference plasma was calculated and the average of the 6 observations was taken as the sulphate uptake ratio. Plasma samples of each child obtained on admission and after nutritional rehabilitation were assayed simultaneously, using the same rat to minimise interanimal variations.

In 7 independent assays normal plasma was used at 0, 2·5, 5, 7·5, 10, 12·5, 15, 17·5, 20% v/v concentrations and log dose response curves were constructed. The relationship was found to be linear up to a concentration of 20% v/v and the index of precision (λ) was 0·18 ± 0·020 (mean ± SE).

Plasma GH was estimated by the double antibody

KAMALA S. JAYA RAO, deputy director

technique of Pennisi (1968), the materials used being similar to those described earlier (Raghuramulu and Jaya Rao, 1974). Plasma albumin was estimated by the biuret method (Wolfson *et al.*, 1948).

Results

The results of the study are presented in the Table. The mean sulphate uptake ratio in children suffering from kwashiorkor was significantly lower than that observed in normal children (P<0·001) and the values rose significantly after nutritional rehabilitation (P<0·01). The mean value in marasmic children was not different from that observed in normal children. However, there was a slight but significant increase after treatment (P<0·05).

The mean basal plasma GH level in children suffering from kwashiorkor was significantly higher than that observed in normal children (P<0·01). The levels came down significantly after nutritional rehabilitation (P<0·05). The mean level in marasmic children was not different from that observed in normal children and there was no change after treatment.

Correlations were tested between sulphate uptake ratio and plasma GH, between sulphate uptake ratio and plasma albumin, and between plasma GH and plasma albumin; both groups of children were tested separately before and after treatment. No positive correlations were obtained in any of the groups when tested individually. As the coefficients of correlation for both groups, before and after treatment, were not significantly different the entire data were combined for analysis. A significant correlation was obtained only between sulphate uptake ratio and plasma albumin concentration (r = 0·576, P<0·001, Figure).

Discussion

Data show that the plasma sulphate uptake ratio is lowered in kwashiorkor. As bioassay of somatomedin involves the stimulation of tissue sulphate uptake in the presence of plasma, the present study may be considered to indicate that plasma somatomedin activity may be lowered in kwashiorkor, an observation in line with that reported by Grant *et al.* (1973). Our data also show additionally that the sulphate uptake ratio is not altered in marasmus. The slight increase after treatment indicates that the reduction, if any, is only marginal. Van den Brande and Du Caju (1973) studied somatomedin activity in malnourished children and although they combined the data obtained from marasmic children with those from children with kwashiorkor, it would appear that both groups had low levels of activity. Their data also indicate the probable presence of a somatomedin inhibitor in the plasma of marasmic children. This was not tested in the present series. The normal sulphate uptake observed in marasmic children could probably be taken as evidence against the presence of such an inhibitor. The presence of an inhibitor in kwashiorkor however is not ruled out.

The finding that plasma GH levels are raised in kwashiorkor but normal in marasmus agrees with our earlier findings (Raghuramulu and Jaya Rao, 1974). There is a consensus regarding the high GH levels in kwashiorkor (Pimstone *et al.*, 1966; Beas *et al.*, 1971; Godard, 1973; Parra *et al.*, 1973; Suskind *et al.*, 1973) but observations on marasmus are discordant (Pimstone *et al.*, 1968; Beas *et al.*, 1971; Godard, 1973; Parra *et al.*, 1973; Suskind *et al.*, 1973). Circulating levels of several proteins known to be synthesised in the liver are markedly lowered in kwashiorkor (Gopalan, 1968). Liver is also one of the sites of somatomedin generation (McConaghey, 1972; Williams and Hughes, 1974). The lowering of somatomedin activity in kwashiorkor might therefore be due to its impaired synthesis, as was suggested by Grant *et al.* (1973).

It has been suggested that plasma amino-acid levels may determine plasma GH concentration in protein calorie malnutrition (Suskind *et al.*, 1973; Jaya Rao, 1974). The possibility that a decrease in somatomedin feedback, either on the pituitary or on the hypothalamus, could also stimulate excess GH production needs to be tested. The lack of correlation between the two substances at the outset precludes such a possibility. On the other hand, it was observed that in all children (except one) who had plasma albumin levels below 2·5 g/100 ml (25 g/l) the sulphate uptake ratio was below 0·7 (Figure). It has earlier been observed that plasma GH levels were raised only when the plasma albumin level fell below this concentration (Raghuramulu and Jaya Rao, 1974). The data of other workers (Pimstone *et al.*, 1968; Samuel and Deshpande, 1972; Lunn *et al.*, 1973) also support the latter observation. The results of the present study indicate that the reduction in sulphate uptake ratio as well as raised plasma GH levels are observed only below a certain threshold level of plasma albumin. They however, do not indicate whether somatomedin activity could be the primary determinant of the raised plasma GH levels in kwashiorkor.

We thank Dr S. G. Srikantia, Director, for his advice and keen interest. We also thank Drs Vinodini Reddy and C. Bhaskaram for letting us study their patients.

Isoniazid liver injury during chemoprophylaxis in children

P. SPYRIDIS, C. SINANIOTIS, I. PAPADEA, L. OREOPOULOS, S. HADJIYIANNIS,
AND C. PAPADATOS
Athens University School of Medicine, Greece

SUMMARY The incidence of INH-associated liver injury was evaluated in 239 children aged between 9 and 14 years, who were receiving 300 mg INH/day for tuberculosis prophylaxis. Serum SGOT and SGPT levels were determined before INH administration and at 4-weekly intervals thereafter. Levels of both enzymes were raised during the first 3 months of treatment in 18 (7·5%) children, while in 23 (9·6%) children either SGOT or SGPT exceeded normal levels (SGOT >40 units, SGPT >30 units). Only 2 (0·8%) children showed SGOT and SGPT values above 100 units and in them treatment with INH had to be discontinued. In all other children transaminases returned to normal during uninterrupted INH administration. It was noted also that transaminase values in children who did not exhibit a rise above normal, still had significantly higher levels during treatment compared with before. The findings of this study suggest that liver injury in children receiving INH for prophylaxis occurs more often than it had hitherto been believed but that it is usually mild and transient.

Isoniazid (INH) has been recognised as a cause of liver injury in patients receiving it. Several studies have shown there is an asymptomatic rise in the level of SGOT in 10–20% of adults given INH (Scharer and Smith, 1969; Bailey *et al.*, 1973; Mitchell *et al.*, 1975), although clinically overt hepatitis appears to be rare in such patients (Martin and Arthaud, 1970; Garibaldi *et al.*, 1972; Moss *et al.*, 1972; Black *et al.*, 1975; Mitchell *et al.*, 1976).

Most studies on the incidence of INH-associated liver dysfunction have been on adults. However Beaudry *et al.* (1974) estimated serum SGOT levels in children aged between 1 and 18 years and found that 6·8% of children receiving INH had higher levels of SGOT 2 months after the start of treatment. As treatment with INH is still used extensively in children, and because there is a lack of information on the incidence and clinical significance of liver injury during INH administration, this study was undertaken.

Materials and methods

The study group comprised 239 schoolchildren (128 boys and 111 girls) 9–14 years old (mean age 11·2). These children had been found to have a positive result to a tuberculin test during routine tests at elementary schools in Athens between November 1976 and March 1977, and they were therefore taking INH.

None of the children had active tuberculosis as shown in chest *x*-rays and by a normal ESR. Each child was given a month's supply of INH, to be taken as a single daily dose of 300 mg, and instructed to return to the clinic each month. Baseline determinations of SGOT and SGPT were obtained immediately before taking the INH and at monthly intervals thereafter.

Serum transaminase levels were determined using a modification of the Reitman and Frankel (1957) colorimetric method (kits from Dade Diagnostic, Inc.). Normal values for this method are 5–40 units for SGOT and 5–30 units for SGPT.

All children were examined for HB_sAg before INH administration. Any patient who subsequently showed an increase in the level of SGOT or SGPT in his or her blood sample was examined for HB_sAg by counterimmunoelectrophoresis and for infectious mononucleosis by the Monosticon test (Organon Teknika).

Results

None of the 239 children had abnormal transaminase concentrations before taking INH.

In 41 (17·1%) of them a rise of at least one transaminase above the normal level was observed during the 12-week period after starting treatment. Two children who showed an increase in SGOT and SGPT but were found to have a positive result in the test for infectious mononucleosis, and 2 others who became HB$_s$Ag positive at the time that transaminase values increased were excluded from the analysis of the data. The increase in enzyme levels that took place during treatment with INH followed three different patterns (Table 1): 18 (7·5%) children showed an increase in both SGOT and SGPT levels. In another 18 children (Table 2) only SGOT increased above 40 units, and in 5 (2·1%) SGPT exceeded 30 units. A rise in the level of SGOT was noted in 36 (15%) children and in 23 (9·6%) children there was an increase in the SGPT level (Table 2).

In children in whom levels of SGOT and SGPT remained normal, an upward trend of the values during the first weeks of treatment was observed (Tables 3, 4). Although the difference between the mean values during each period of observation was small, the statistical analysis (paired *t* test) showed that it was highly significant (P<0·001).

The rise in the levels of enzymes took place during the first 2 months of treatment in most children (Table 4), but generally it was mild and transient. Only 2 (0·8%) children were found to have SGOT and SGPT values above 100 units and INH had to be discontinued. In the remaining 39 cases treatment was continued, but with close supervision and frequent monitoring. In these children the transaminases returned to normal levels within 4–8 weeks.

SGPT	23	13	(57)	8	(35)	2	(8)

Discussion

These data confirm earlier observations—made mainly in adults—that some patients receiving INH may develop high levels of serum transaminase without overt signs of liver disease (Scharer and Smith, 1969; Bailey *et al.*, 1973; Mitchell *et al.*, 1975).

In most previous studies patients were monitored for liver injury by determination of one transaminase. The incidence of abnormal SGOT values in these studies ranged from 10 to 20% of the patients taking the drug (Byrd *et al.*, 1972; Bailey *et al.*, 1973; Mitchell *et al.*, 1976).

In a similar study in 178 adolescents SGPT values became abnormally high in 10% of patients within 10 weeks of taking INH (Litt *et al.*, 1976).

Until recently no data of hepatic function had been reported in children receiving INH for prophylaxis and the *ad hoc* Committee on Isoniazid and Liver Disease in Atlanta, Georgia, USA, stated in a report issued in 1971 that 'isoniazid-associated liver disease does not appear to occur in children.' Since then reports have suggested that severe hepatic injury (Rudoy *et al.*, 1973) or even death (Vanderhoof and Ament, 1976) might occur in children taking INH. Beaudry *et al.* (1974) who studied SGOT levels in 369 children on INH prophylaxis reported increased levels of SGOT in 6·8% of them.

In the present study in which both SGOT and SGPT concentrations were monitored, a rise above normal values for both enzymes was detected in 18 (7·5%) out of the 239 children. In addition 23 (9·6%) more children showed an increase either in SGOT or SGPT, during the period of observation (Table 1). The incidence of 17·1% for children with raised transaminase values is significantly higher than the 6·8% incidence reported by Beaudry *et al.* (1974). The reason for this difference is not clear and it could be due to differences in the techniques used to determine enzyme levels. It is evident that it is difficult to compare data from different studies. More studies using strict criteria are needed.

Another interesting finding in the present study was that higher values of SGOT and SGPT were noted in most patients compared with levels before treatment (Tables 2, 3). Although this difference was small, the statistical analysis (paired *t* test) showed that it was highly significant ($P<0\cdot001$). This finding, not reported by others, suggests that liver injury is more common than is shown by an increase in the level of enzymes. It has been suggested that the degree of liver injury may be greater if INH is given at the same time as enzyme-inducing drugs such as rifampicin (Pessayre *et al.*, 1977).

It is apparent from previous studies, and confirmed by this one, that most patients with subclinical hepatic damage recover completely while continuing on INH, and do not progress to overt hepatitis. The fact that in the present study only 2 patients had a rise of SGOT and SGPT above 100 units and had to stop taking INH, while 39 children were able to continue to take it and their SGOT and SGPT levels returned to normal, shows that although INH prophylaxis is rarely associated with clinically significant liver injury, transaminase levels should be monitored in the first month of treatment to detect patients who might be susceptible to liver damage.

Short reports

Delayed diagnosis of congenital anal stenosis

E. M. KIELY, R. CHOPRA, AND J. J. CORKERY

Department of Paediatric Surgery, Children's Hospital, Birmingham

SUMMARY The consequences of a delayed diagnosis of congenital anal stenosis in 11 children are described. A plea is made for proper anal examination in the newborn, the technique for which is described.

Congenital abnormalities of the anus are easily detected. Nevertheless the diagnosis is sometimes missed, with serious consequences for the child. Between 1970 and the end of 1977, 11 children with minor congenital anal abnormalities, in whom the diagnosis was initially missed, were seen on one surgical firm at this hospital (Table 1).

After diagnosis and initial treatment intravenous urography was performed on each child; bilateral hydronephrosis and hydroureter due to posterior urethral valves were present in one patient (Case 11). The urograms were normal in all the others.

Treatment and results

All the children were treated surgically. Nine required anoplasty followed by dilatations. In the remaining 2 limited courses of anal dilatation were sufficient. The results are summarised as either 'satisfactory' (Table 2) or 'unsatisfactory' (Table 3). The 'unsatisfactory' group all have persistent constipation with occasional faecal impaction; all require laxatives and, between them to date, they have had 17 hospital admissions. Four have had contrast enemas confirming the presence of a persistent megarectum. Two cases may be quoted.

Table 1 *Details of 11 cases of anal stenosis*

Case	*Sex*	*Age (months)*	*Presenting complaint*	*Anomaly*
1	M	42	Faecal incontinence	Covered anus and skin tags
2	M	5	Constipation	Anal stenosis
3	F	5	Constipation; abdominal mass	Anal stenosis
4	F	6	Constipation	Anal stenosis
5	F	7	Abdominal mass	Anal membrane; stenosis and skin tags
6	F	5	Abdominal distension; diarrhoea	Anal stenosis
7	F	4	Constipation	Covered anus
8	F	4	Rectal bleeding	Anal stenosis and skin tags
9	M	1	Oseophageal atresia	Anal stenosis
10	M	1½	Abdominal distension	Covered anus
11	M	1	Constipation	Covered anus

Case 1. A boy aged 3½ years was referred because of overflow rectal incontinence. On inspection of the anus a congenital abnormality was obvious (Fig. 1). The obstructing rigid hood of skin was excised (Fig. 2).

Case 6. A 5-month-old baby girl presented with abdominal distension and diarrhoea. Before being seen by us a barium enema had been performed but the anus had not been examined. The enema showed an appearance compatible with Hirschsprung's

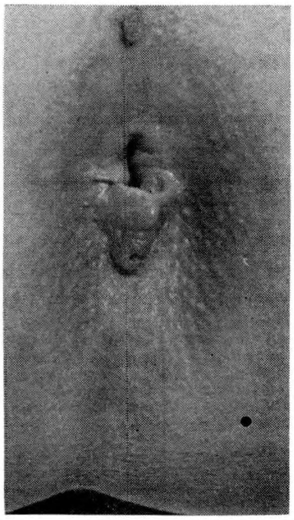

Fig. 1 *Anal abnormality is obvious on inspection.*

disease (Fig. 3) and it was for this reason that a surgical opinion was sought. The anus looked normal but on attempting digital examination a tight stenosis at the dentate line was detected. Rectal biopsy was normal.

Table 2 *'Satisfactory' group*

Case	*Age at presentation (months)*	*Functional result*	*Duration of treatment needed (months)*
7	4	Normal	2
8	4	Normal	4
9	1	Normal	3
10	1½	Normal	7
11	1	Normal	3

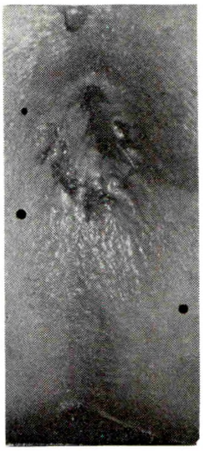

Fig. 2 *Obstructing skin has been excised.*

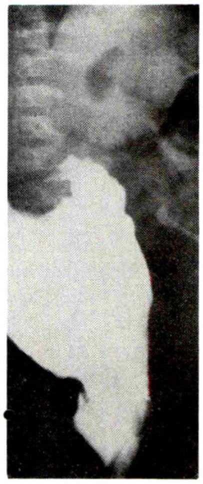

Fig. 3 *Barium enema (Case 6). Appearance is compatible with Hirschsprung's disease.*

Table 3 *'Unsatisfactory' group*

Case	*Age at presentation (months)*	*Functional result*	*Duration of treatment to date (months)*
1	42	Unsatisfactory	12
2	5	Unsatisfactory	54
3	5	Unsatisfactory	11
4	6	Unsatisfactory	18
5	7	Unsatisfactory	21
6	5	Unsatisfactory	12 then lost to follow-up

Discussion

Although classed by us as a minor abnormality, anal stenosis, if neglected, becomes a major one requiring prolonged surgical treatment and supervision. The longer the stenosis is untreated the more severely affected the rectum becomes so that in the worst cases the rectum becomes grossly distended, insensitive, and apparently aperistaltic (Fig. 4). This constitutes a severe disability, the treatment is prolonged and major surgery may be needed. Our results (Tables 2 and 3) and the experience of others (Partridge and Gough, 1961; Stephens and Smith, 1971; Taylor *et al.*, 1973) show that the sooner the diagnosis is made and effective treatment instituted, the better the prognosis.

In 3 of these children simple inspection of the anus was sufficient to reveal an abnormality requiring closer scrutiny. However, the anus can look perfectly

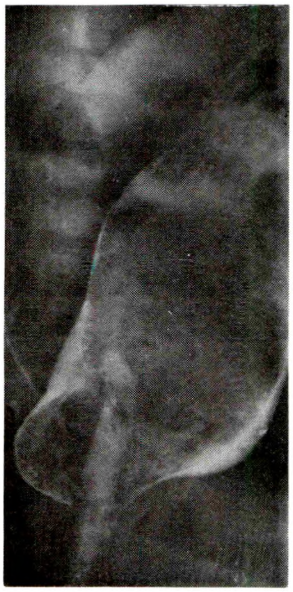

Fig. 4 *Barium enema in Case 5 showing huge megarectum full of faeces.*

normal and yet be severely stenosed. The normal passage of meconium and stools is not a reliable guide to the state of the anus, as a stenosed anus will often allow meconium and the soft stool of the newborn to escape. Similarly a rectal thermometer can usually be easily introduced into the rectum in these cases.

The technique of anal examination in the newborn is easy. The anus should first be inspected and then palpated. The little finger, well lubricated, should be used. The finger is inserted into the anus, pad first, very slowly and very gently. The normal anus will stretch as this is done and in most cases a little finger can enter the rectum. However, the examiner's finger may be too big or, as in the case of a very small baby, it may obviously be unwise to over dilate and injure the anus. With practice all degrees of anal stenosis can be excluded without the finger tip entering the rectum. During the palpation two points in particular should be noted. Firstly, the absolute size of the anus. More important than this is the suppleness or otherwise of the canal. A rigid anal canal is an abnormal one.

The anus is easily amenable to examination in the newborn. If there is any doubt that there is even a slight element of stenosis an expert surgical opinion should be urgently obtained.

Acute anuric renal failure in an infant with systemic candidiasis

J. Z. HECKMATT, S. R. MEADOW, AND C. K. ANDERSON

Department of Paediatrics, University of Leeds, Seacroft Hospital, and the University Department of Pathology, General Infirmary, Leeds

SUMMARY We report a newborn baby who presented with acute anuric renal failure resulting from systemic candidiasis. The predisposing factors and diagnostic features are examined.

Although the newborn baby is susceptible to infection and mucocutaneous thrush is common, systemic candidiasis is rare. When it does occur in babies it usually causes osteomyelitis, arthritis, and meningitis. Renal failure is not a recognised feature.

Case history

A boy was born in August 1977 at 29 weeks' gestation, birthweight 1.430 kg. Respiratory distress syndrome developed and he required ventilation for 23 days. A blood culture taken at 2 days grew *Staphylococcus aureus* and he was given ampicillin and cloxacillin. Subsequently he received courses of gentamicin and carbenicillin.

He was fed intravenously from 3 to 22 days of age via silastic cannulae. These were placed in various veins, including the left long saphenous. At 21 days the long saphenous site became infected and blood cultures grew *Candida albicans*. The cannula was therefore removed. Five days later 3 ml pus was drained from the abscess; Gram's stain showed yeast cells and mycelial elements; cultures produced a profuse growth of *C. albicans*. He was given benzylpenicillin, streptomycin, and lincomycin from 25 to 30 days and the abscess healed. Thereafter he made good progress and for 5 weeks he fed normally and gained weight. Five blood cultures during this period were sterile.

When he was 64 days old he suddenly became anuric and was transferred to Leeds. There was no urine in the bladder on catheterisation. An intravenous urogram showed nephrograms of 2 normal size kidneys which failed to excrete dye into the renal pelvis. A cystogram was normal; there was no urethral obstruction and no vesico ureteric reflux. After a week of anuria blood tests showed: Hb 6.4 g/dl, WBC 14.8 × 10^9/l (14 800/mm^3) (75%

neutrophils, 24% lymphocytes), normal platelets, and no evidence of disseminated intravascular coagulation; plasma urea 20 mmol/l (120 mg/100ml), K 6.3 mmol/l.

In order to find out if recovery was likely, and if dialysis was justified, the baby was given an open renal biospy on day 71. Macroscopically the kidney looked mildly oedematous. The renal pelvis felt normal and contained no obstructing mass. On microscopical examination the renal tissue appeared viable, so peritoneal dialysis was begun the next day and continued for 3 days. Further study of the sections showed *Candida* within the kidney. Intravenous 5-fluorocytosine therapy was begun with 200 mg/kg per day initially. Blood levels a thousand times the minimum inhibitory concentration (MIC) of the *Candida* were obtained (MIC 0·15 mg/dl). Two days later he began to pass urine which on microscopical examination contained budding yeast cells and hyphae (Fig. 1).

During this time he also had extensive bronchopneumonia and required further ventilation. The blood culture grew *C. albicans*. There was clinical improvement, the pneumonia resolved and he continued to pass urine. The blood cultures remained positive although the *Candida* in the blood was allegedly sensitive to fluorocytosine. For a while clinical improvement was maintained, but he deteriorated suddenly to die at 86 days of septicaemia.

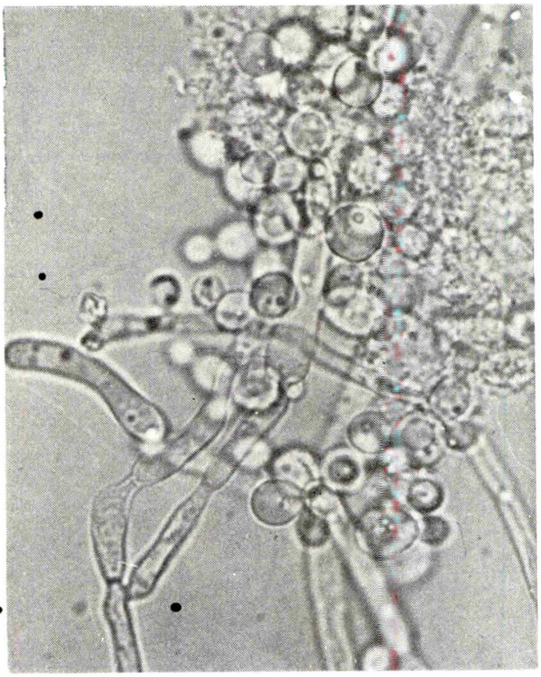

Fig. 1 *Unstained urine HP × 100. Budding yeast cells and hyphae.*

Renal biopsy (Fig. 2)

A total of 65 glomeruli was seen per section, none being hyalinised or scarred. There was a marked dilatation of Bowman's space in 20%. The tubules were preserved but showed marked epithelial, cloudy swelling, and focal dilatation. At two points there were small foci of necrosis involving tubules and interstitium, accompanied by mixed inflammatory cell infiltration (Fig. 2). Along the side of the biopsy, but not within the areas of necrosis, were abundant fungal filaments which were PAS- and Gram-positive and which stained positively with Grocott's stain for fungi (Fig. 1). These filaments had the morphology of *C. albicans*. It was considered that the biopsy revealed viable renal tissue which showed toxic and reactive changes, probably due to renal infection with *C. albicans*.

Necropsy

The right kidney. This had become a pyonephrosis and was about 4 times normal size. There was a pronounced reduction in renal tissue in some areas and the lower lobe was infarcted.

The left kidney. This was a little enlarged. Small white abscesses were scattered throughout the parenchyma and there were areas of *Candida* in the interstitium. There was a large abscess, 1 cm across, occupying the lower lobe.

Discussion

It is unusual for an apparently healthy baby to develop acute renal failure. The total anuria suggested urinary tract obstruction, but that was excluded by the urogram and cystogram. Intrinsic renal disease was the only alternative. Acute tubular necrosis or renal venous thromboses were unlikely because of the immediate good health of the baby. Despite intensive investigation the cause was not found until *Candida* was identified in the renal biopsy tissue. It is possible that the anuria was a result of intrarenal obstruction by fungal growth in the renal tubules. Alternatively an 'acute pyelonephritis' shutdown might have occurred from fungal infection.

Systemic candidiasis in infants usually presents as osteomyelitis, arthritis, and meningitis (Businco *et al.*, 1977). In most cases the infant is premature and receiving antibiotics. A vein has usually been catheterised for intravenous feeding (Boeckman and

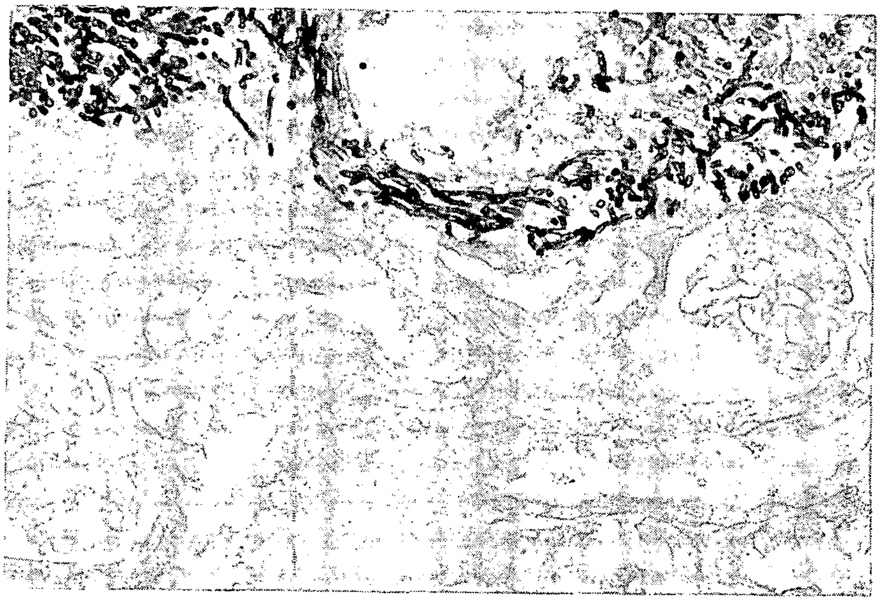

Fig. 2 *Renal biopsy (Grocott's stain 285). Positively-staining filaments of Candida albicans are seen at the edge of the renal cortical tissue. Two glomeruli are seen, one on the lower left-hand side, the other on the right.*

Krill, 1970). Systemic candidiasis is rare in the healthy infant. However, with the increase in intensive care of the newborn systemic candidiasis may become more common. For effective treatment early diagnosis is essential and there may be clues: the growth of *Candida* from a cannula tip, or the appearance in the urine of budding yeast cells and, in particular, hyphae (Bernhardt *et al.*, 1974). Indeed urine examination and cultures may be a more reliable method of diagnosis than venous blood culture (Stone, 1974).

Candida infection of the urine, although rare, may occur at any age. Most urine infections are not accompanied by systemic candidiasis or by renal involvement (Littlewood, 1968). Gherardi (1965) reported a baby who presented with severe hypertension resulting from renal artery fungal obstruction. Acute renal failure has not been considered a complication of either systemic or urinary candidiasis in children, although there are reports of its occurrence in adults (Louria *et al.*, 1962; Lehner, 1964).

We thank Dr John Davies for the information about the infant's early life, and Dr Evans and Dr Mason for technical help. We acknowledge, with gratitude, the sustained efforts of the nursing and medical staff in Grimsby and Leeds; their help so nearly succeeded in saving the baby.

Leukaemic hypopyon in acute lymphoblastic leukaemia after interruption of treatment

G. MASERA, V. CARNELLI, C. UDERZO, C. TOSELLI, F. LASAGNI,
AND E. LAMBERTENGHI

Departments of Paediatrics and Clinical Ophthalmology, University of Milan School of Medicine, Italy

SUMMARY A 7-year-old girl was successfully treated for acute lymphoblastic leukaemia, and remained in remission after treatment had been completed in 3 years. Four months after cessation of treatment, iridocyclitis with hypopyon developed in one eye. Exudate from the anterior chamber contained numerous lymphoblasts. Local radiotherapy led to complete resolution of the ocular lesions, and the patient remains well 22 months later.

Leukaemic involvement of the retina, optic nerve or, occasionally, of the anterior chamber of the eye, was recorded by Ridgway *et al.* (1976) in 9% of acute lymphoblastic leukaemia (ALL) cases in children, and is often demonstrable at necropsy (Sansone and Mariotti, 1953; Allen and Straatsma, 1961; Evans, 1964; Kearney, 1973; Mark *et al.*, 1974; Ridgway *et al.*, 1976; Murray *et al.*, 1977). We describe hypopyon as an isolated occurrence in a case of ALL 4 months after treatment had been stopped.

Case report

A 7-year-old girl with ALL was treated with vincristine 2 mg/m^2 weekly for 5 weeks, together with prednisone 50 mg/m^2 daily for one month, and full remission was obtained. CNS prophylaxis was then given with 2400 rads of ^{60}CO cranial irradiation in 24 days, and intrathecal methotrexate 6 mg/m^2 weekly for 6 weeks, repeated every 3 months for the next 18 months. Remission was maintained on 6–mercaptopurine (6–MP) 50 mg/m^2 daily and methotrexate 20 mg/m^2 weekly. Reinduction therapy was given every 3 months: vincristine 1·5 mg/m^2 weekly for 3 weeks; prednisone 30 mg/m^2 daily for 3 weeks. After 3 years of complete remission, treatment was stopped in April 1976.

Four months later, while still in complete haematological remission, our patient complained of severe photophobia. The left eye showed perikeratic injection, infiltration and congestion of the iris, and copious whitish hypopyon which occupied almost half of the anterior chamber; there was absence of synechiae, little aqueous flare, and the pupil was round central and reacting. The right eye was normal. The haematological findings remained normal, as did the bone marrow biopsy and the cerebrospinal fluid (CSF). A diagnosis of iridocyclitis was made, and local treatment with atropine and cortisone, with antibiotics and dexamethasone systematically, was begun.

Within 3 weeks there was complete regression of the ocular lesions and treatment was stopped. Two months later the ocular condition recurred in the left eye. The same treatment was repeated, but after 10 days there had been no improvement, and a subconjunctival injection of betamethasone was given. During the next 10 days there was progressive absorption of the hypopyon with some residual swelling of the iris. The eye returned to normal after a further month of local treatment (atropine and cortisone).

Two months later there was a second relapse with similar appearances of the left eye, this time with haemorrhagic striae mixed with the hypopyon. Treatment (atropine, cortisone locally, and subconjunctival injection of betamethasone) resulted only in some relief of symptoms, but shortly afterwards there was copious hypopyon. Fluid was then withdrawn from the anterior chamber of the left eye and this showed a cell population composed mainly of lymphoblasts. Bone marrow and CSF remained normal. A diagnosis of leukaemic hypopyon was made. Radiotherapy (total of 390 rads in a 22-day period) to the anterior segment of the eye was given and resulted in complete remission. Further systemic treatment (vincristine and prednisone, followed by 6–MP and methotrexate) was then given.

After 22 months, the clinical and haematological findings remain normal.

Discussion

Ridgway *et al.* (1976) suggested that the eye, because of its anatomical structure, can behave as a 'pharmacological sanctuary' in leukaemia. The anterior segment is the most rarely affected site within the eye, but a few other cases have been reported (Kearney, 1973; Mark *et al.*, 1974; Murray *et al.*, 1977). In all these reported cases however, this complication occurred during haematological relapse or in association with meningeal leukaemia. In our case the patient was off treatment and there were no other leukaemic manifestations.

Although radiotherapy to the eye proved effective, a case such as this must be regarded as having relapsed and therefore requiring further courses of antileukaemic drugs.

We thank Professor F. Fossati who performed ocular radiotherapy.

Reye's syndrome associated with respiratory syncytial virus infection

N. GRIFFIN, J. W. KEELING, AND A. H. TOMLINSON

Department of Paediatrics and Pathology, John Radcliffe Hospital, and the Virology Laboratory, Churchill Hospital, Headington, Oxford

SUMMARY An upper respiratory tract infection in a 22-month-old boy was followed by rapid loss of consciousness, hypoglycaemia, uraemia, and death. Necropsy examination showed fatty change of liver and kidneys, severe cerebral oedema, bronchiolitis, and endocardial fibroelastosis affecting the left ventricle. Immunofluorescence staining showed infection with respiratory syncytial virus (RSV). The clinical and pathological findings were those of Reye's syndrome, not previously reported accompanying RSV infection.

Reye *et al.* (1963) described a syndrome of acute encephalopathy and fatty degeneration of the viscera. The association with an acute respiratory virus infection has often been noted, but respiratory syncytial virus (RSV) has not, to our knowledge, been implicated. We report a fatal case of Reye's syndrome associated with a RSV infection.

Case report

A boy of 22 months developed a mild upper respiratory tract infection with nonproductive cough and coryza which was treated with a proprietory linctus. On the 3rd morning he did not wake at the usual time but was seen by his mother at 8.30 a.m. to be sleeping peacefully with normal respirations. At 9.30 a.m. she found him blue, limp, and dyspnoeic.

On admission one hour later he was found to have peripheral vasoconstriction, central cyanosis, and to be in shock. Systolic blood pressure was 60 mmHg, pulse 88/min, and respiratory rate 48/min. He responded only to painful stimuli, his respirations were shallow, noisy, and irregular. There was diminished air entry, particularly on the left, coarse moist sounds and expiratory rhonchi were present bilaterally. The liver was not palpable. Retinal examination and reflexes were normal. His condition deteriorated rapidly; coma deepened, muscle tone increased, plantar responses became extensor. Treatment with dextrose/saline, hydrocortisone, antibiotics, and oxygen was ineffective; he died 3 hours after admission.

Investigations. Total WBC count 18 800/mm^3 (18·8 × 10^9/l) with mild neutrophilia, blood urea 69 mg/100 ml (11·5 mmol/l), bicarbonate 17 mEq/l, blood sugar 10 mg/100 ml (0·56 mmol/l), CSF and blood cultures were sterile. Nose and throat swabs yielded normal flora.

Necropsy. A well nourished baby boy 89 cm crown/heel length, weighing 11·6 kg. The brain was swollen (1170 g); slicing after fixation showed obliteration of sulci. The larynx was injected, trachea and main bronchi contained purulent mucus, and the epithelium was swollen and purplish. The lungs were bulky with petechial haemorrhages and foci of collapse throughout (right 110 g, left 102 g). The heart was slightly enlarged (64 g) but anatomically normal, left ventricular hypertrophy and dilatation with pearly white thickening of the left ventricular endocardium was present, valves healthy. The liver was enlarged (554 g), pale yellow, and greasy to touch. Other organs were healthy.

Histological examination of the liver showed gross fatty change throughout the lobules and fat droplets present in renal tubular epithelium. In the lung, bronchi and bronchioles were plugged with mononuclear cells, lining epithelium was cuboidal, and the wall infiltrated by inflammatory cells with patchy extension into alveoli. A subendocardial layer of fibroelastic tissue was present in the left ventricle. There was cerebral oedema but no inflammatory cell infiltration of brain or meninges.

Virological investigation. Secretions aspirated from the nasopharynx, on admission, were inoculated on to tissue cultures on monkey kidney, human amnion, and Hep 2 cells. No virus was isolated. Cells from the aspirate stained by the immunofluorescence technique of McQuillin and Gardner (1968) showed specific fluorescence for RSV.

Brain tissue collected at necropsy was inoculated on to human amnion and monkey kidney cells, but no virus was isolated. Post-mortem lung also failed to yield virus when cultured on the same cells as the aspirate. A piece of lung, 10 × 10 × 5 mm, was snap frozen and sections, 6 μm thick, were cut in a cryostat, air-dried, and fixed with acetone. Sections were stained for RSV using bovine antiviral serum* (1:80) and fluorescein conjugated rabbit antibovine globulin* (1:40). Control sections were treated with bovine serum free of antibody. In each test section there were 2 or 3 small bronchi with fluorescent cells in the epithelium (Figure); no such fluorescence appeared in the control sections.

Complement-fixation tests on serum collected at necropsy gave the following titres: parainfluenza virus 1:16; mumps 1:8; RSV influenza A, *Mycoplasma pneumoniae*, psittacosis, *Coxiella burnetii*, herpes simplex virus, and cytomegalovirus all 1:8.

Discussion

The aetiology of Reye's syndrome is still uncertain. An association between it and various drugs and chemicals has been reported (Glasgow and Ferris, 1968; Shield *et al.*, 1977) but there does not seem to be an association with a particular molecular configuration. The frequency of a mild prodromal illness may partly explain the association with salicylate ingestion, although in one report several children were taking high doses of salicylate (Linneman *et al.*, 1975). Aflatoxin ingestion has been incriminated in some countries, but its precise role is unknown (Hogan *et al.*, 1978). The most commonly reported association is that of Reye's syndrome and virus infection. Influenza B virus is the most often implicated although in some cases infection with influenza A, parainfluenza, and adenovirus or varicellazoster virus has been shown by isolation or serology (Linneman *et al.*, 1975). In this case, RSV was demonstrated by immunofluorescence but was not isolated in tissue culture, which is not unexpected as this virus is difficult to grow from necropsy specimens. The histological appearances of the lungs in this child are typical of bronchiolitis. The presence of endocardial fibroelastosis may have contributed to this boy's death; some children with this condition die suddenly and unexpectedly, but many more are precipitated into heart failure by an apparently trivial infection. Heart failure alone would not be expected to produce severe panlobular fatty change in the liver but rather a centrilobular distribution of fatty change, possibly associated with necrosis. Similarly, renal tubular fatty change could not be attributed to heart failure.

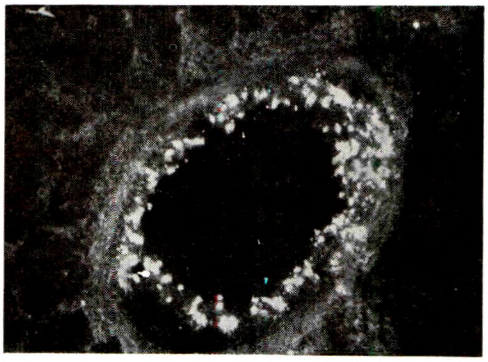

Figure *Immunofluorescence staining of RSV antigen in the epithelial cells of a small bronchus.* (× *180*).

Reye's syndrome has not been reported previously as a complication of RSV infection and it is perhaps of particular interest that a bronchiolitis rather than a pneumonia is present in this case, in view of the suggestion that bronchiolitis is an allergic response to a virus antigen (Gardner *et al.*, 1970). The association of Reye's syndrome with a variety of virus infections and the absence of viral invasion of brain or liver suggests the participation of an additional factor, metabolic or toxic, in the pathogenesis of this condition.

Chloramphenicol and phenobarbitone—a drug interaction

R. A. BLOXHAM, G. M. DURBIN, T. JOHNSON, AND M. H. WINTERBORN

Department of Paediatrics, East Birmingham District General Hospital, Birmingham

SUMMARY Two infants with meningitis who were treated with phenobarbitone and high-dose chloramphenicol showed progressive falls in the peak blood levels of chloramphenicol. A standard chloramphenicol dose of 50 mg/kg daily would have produced subtherapeutic blood levels after only a few days. The importance of measuring serial blood chloramphenicol concentrations is stressed.

Infants and young children with bacterial meningitis are often treated with phenobarbitone to prevent convulsions. Chloramphenicol is the antibiotic of choice for the treatment of *Haemophilus influenzae* meningitis. A possible interaction between these two drugs is recognised (Bella *et al.*, 1968) but has not been specifically reported in man. We therefore report two infants with *H. influenzae* meningitis treated with phenobarbitone and chloramphenicol, in whom peak blood levels of chloramphenicol decreased with time in spite of maximum recommended dosage. The first case alerted us to the problem, the second prompted a more detailed study.

Case reports

Case 1. This 7-month-old girl presented with a 4-day history of upper respiratory infection, followed on the day of admission by fever, lethargy, irritability, and refusal to feed. Cultures of blood and CSF gave a pure growth of *H. influenzae*, sensitive to chloramphenicol. She was treated with IV chloramphenicol succinate (100 mg/kg per 24 h) plus phenobarbitone (10 mg/kg per 24 h). Blood chloramphenicol concentration was measured by bioassay based on the method described by Louie *et al.* (1976). Peak blood chloramphenicol levels were 31 mg/l on days 2 and 3 but they fell to less than 5 mg/l on day 5. On day 6 oral treatment with pure chloramphenicol in the same dose was substituted. On day 8 the peak blood level was still <5 mg/l and the dose of chloramphenicol was therefore doubled (200 mg/kg per 24 h). Subsequently, peak blood levels of between 7 and 11 mg/l were maintained until day 23, when treatment was stopped. Her subsequent progress was unremarkable and she remains in good health 12 months later.

Case 2. This 3-month-old boy presented with a one-day history of vomiting, fever, lethargy, and irritability culminating in a brief convulsion. Cultures of blood and CSF gave a pure growth of *H. influenzae*, sensitive to chloramphenicol. He was treated with IV chloramphenicol succinate (100 mg/kg per 24 h) for 8 days, before being changed to oral pure chloramphenicol in the same dosage. He was treated throughout his illness with phenobarbitone (10 mg/kg per 24 h). Chloramphenicol was given for a total of 19 days and he made a full recovery. Although chloramphenicol blood levels were initially satisfactory, they fell rapidly during the first few days of IV treatment (Figure). The biological half-life of chloramphenicol fell from 7 h 18 min on the 3rd day to 4 h 6 min on the 5th.

Discussion

90% of chloramphenicol is inactivated in the liver either by conjugation with glucuronic acid or by reduction to aryl amines before being excreted in the urine. The remaining 10% is excreted unaltered in the urine. In these two infants there was a rapid

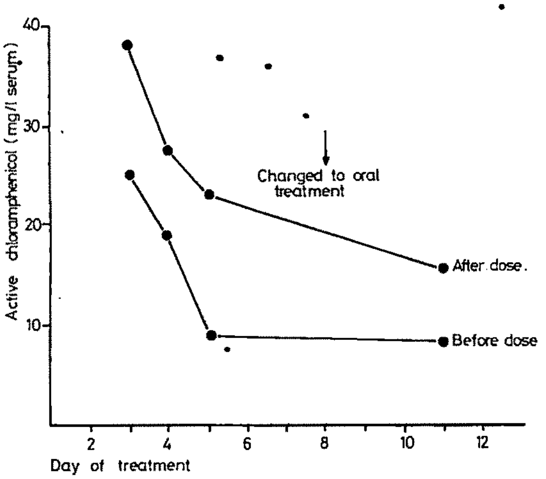

Figure (*Case 2*) *Blood levels of active chloramphenicol during treatment with chloramphenicol 100 mg/kg per 24 h plus phenobarbitone 10 mg/kg per 24 h. Blood levels were measured before and one hour after the 12 midday dose.*

decline in chloramphenicol blood levels despite sustained IV treatment in high dosage. This decrease is probably explained by the induction of hepatic microsomal enzymes by phenobarbitone. Increased glucuronidation of chloramphenicol and a consequent decrease in therapeutic activity have been demonstrated in rats pretreated with phenobarbitone (Bella *et al.*, 1968).

The conventional chloramphenicol dose for meningitis and septicaemia is 50–100 mg/kg per 24 h in infants and children. A lower dose is usually recommended for neonates whose renal and liver immaturity delays chloramphenicol excretion, but Black *et al.* (1978) showed that doses of up to 95 mg/kg per 24 h may be needed to maintain therapeutic blood levels in this age group also. Our two patients show that during treatment with phenobarbitone even the maximum recommended dose of chloramphenicol, 100 mg/kg per 24 h, may be insufficient to maintain peak blood levels within the therapeutic range 15–25 mg/l. We therefore recommend that in all patients who receive enzyme-inducing anticonvulsants (Conney, 1967), chloramphenicol blood levels should be measured every one or 2 days to avoid the hazards of excessive or inadequate dosage. It is possible that newer anticonvulsants with less enzyme-inducing activity, such as sodium valproate, will prove to have less effect on chloramphenicol metabolism than phenobarbitone.

We thank Mrs Barbara Tennant for secretarial help.

Food allergy

Response to treatment with sodium cromoglycate

J. B. G. WATSON AND J. TIMMINS

Departments of Paediatrics and Pharmacy, Children's Hospital, Sheffield

SUMMARY Two children with food allergy could not be successfully managed on dietary restriction alone. There was a good response to treatment with oral sodium cromoglycate but none to placebo treatment. The use of sodium cromoglycate in the management of food allergy should be studied further.

Allergy to cows' milk and other foodstuffs presents a difficult problem in diagnosis and management in children. Diagnostic criteria were discussed by Walker-Smith (1975). Reports by Freier and Berger (1973) and Kuzemko and Simpson (1975) suggested that treatment with oral sodium cromoglycate might relieve symptoms. Two children are reported who demonstrated specific food intolerance, and their response to treatment with oral sodium cromoglycate is described.

Case reports

Case 1. A baby girl was breast fed for the 1st month of life and subsequently was given a dried milk (Ostermilk). After the change to artificial feeding her weight gain was unsatisfactory and she had persistent respiratory symptoms. When the patient was one-year old, her mother concluded that the child was allergic to milk and discontinued milk feeds. There was an almost immediate cessation of symptoms and her rate of weight gain returned to normal. She returned to milk-containing products in her diet at age 2 years. After this she developed eczema which did not respond well to local treatment. She had recurrent episodes of abdominal pain and loose stools. Attempts to eliminate milk from her diet were unsuccessful as she had access to milk products in neighbours' houses and from other children. Eczema, abdominal pain, and diarrhoea were her most significant symptoms and their severity was related to ingestion of milk products or milk. Immunoglobulin studies showed a slightly raised serum IgE of 240 IU/ml (normal 20–120 IU/ml) at age 4½ years. C3, C4, and C1 INH were normal.

Treatment with oral sodium cromoglycate 100 mg four times daily was begun at age 4½. After one year there was a significant improvement in her overall state of health. The eczema had disappeared; her previously dry and ichthyotic skin became normal. Her diet at this time included milk-containing products—butter, bread, coffee, cakes, milk chocolate—and these were well tolerated without adverse reaction. Her weight had increased from the 3rd to the 10th centile. After one year it was decided to test her dependence on the treatment in the hope that it could be discontinued. Therefore, alternate episodes of treatment with sodium cromoglycate capsules and placebo capsules were given. During the period of placebo treatment, her eczema and gastrointestinal symptoms returned and she became a miserable, irritable child. During treatment with sodium cromoglycate she remained well. It was therefore decided that she should continue with the sodium cromoglycate orally indefinitely.

Case 2. A boy had severe eczema from age 2 years. He developed asthma at 7 and at about this age had a severe urticarial rash on several occasions. The rash was related to the ingestion of certain foodstuffs: pork, bacon, tomato soup, sage and onion stuffing, fish. Serum immunoglobulin and complement studies were normal. In view of the history he was given 100 mg sodium cromoglycate orally before ingestion of a known allergen (sage and onion stuffing) and he developed a mild urticarial reaction. He was subsequently given 200 mg oral sodium cromoglycate and after ingesting the same allergen he had no reaction. He was next treated for one week with sodium cromoglycate 200 mg orally, four times daily. Then, after a week of no treatment he was treated with placebo. During the period of treatment with sodium cromoglycate he had no episodes of urticaria, but while taking the placebo these occurred severely each day (Table). He has since remained on sodium cromoglycate 200 mg orally, four times daily. His eczema has resolved and he has no episodes of urticaria, except when he forgets his treatment. On starting the sodium cromoglycate he had transient mild swelling of his face which settled in a few days.

Table (*Case 2*) *Response to treatment with sodium cromoglycate* (*oral*)

Sodium cromoglycate (oral)	*Allergens*	*Response*
None	Sage and onion stuffing	Severe urticaria
100 mg	,, ,, ,,	Mild urticaria
200 mg	,, ,, ,,	None
200 mg 4 times daily × 1/52	Bacon	Mild
	Tomato soup	Mild
Placebo × 1/52	Fish Bacon Pork	Brisk reactions each day

Discussion

The range of symptoms which can occur as a result of exposure to food allergens include anaphylactic shock, asthma, rhinitis, urticaria, eczema, and gastrointestinal disturbances (Blanckaert *et al.*, 1975). The clinical diagnosis was established by the absence of symptoms after dietary elimination of the allergen, and recurrence of symptoms after reintroduction of the allergen. Elimination of specific allergens from the diets of young children is difficult to achieve as the child will accept food given to him by other children, neighbours, and friends unaware of the restrictions. Oral sodium cromoglycate offers a possibility of protection from food allergens as its mechanism of action lies in the inhibition of degranulation of mast cells, preventing the release of histamine and slow reacting substance A (Werthenschlag, 1975). It has been reported (Moss *et al.*, 1971) that less than 2% of orally-administered sodium cromoglycate is absorbed. It is probable that allergic symptoms are prevented by the unabsorbed portion of the drug passing through the gut. No large-scale study has been reported on the use of oral sodium cromoglycate in the management of cows' milk or other food allergy, but these observations demonstrate its usefulness in specific cases.

We thank Professor R. D. G. Milner for help and permission to present these cases, Fisons Ltd for supplies of oral sodium cromoglycate, and Drs A. Milford Ward and J. Watkins of the Department of Immunology, Hallamshire Hospital, Sheffield.

Renin and aldosterone response in human newborns to acute blood volume change

Sir,

We read with interest the report of Dillon and associates (*Archives*, 1978, **53**, 461) on this subject. In a paper to be submitted to *Rivista Italiana Pediatria* we studied plasma renin activity (PRA) in 13 newborn infants undergoing exchange transfusion with ACD stored blood for hyperbilirubinaemia of various aetiology during the first 6 days of life. Exchange transfusions were such that the infants were kept normovolaemic. Weights ranged from 2400 to 3810 g, and gestational ages from 37 to 41 weeks. PRA and haematocrit were determined on umbilical vein samples before, midway, and at the end of the procedure, and from the transfused blood. The amount of blood administered ranged from 63.7 to 155.8 ml/kg, and the exchange rate from 0.964 to 5.288 ml/kg per min.

Statistical analysis of data was performed by a step-wise multiple regression program (UNIVAC 90/30), taking into account as dependent variable the average rate of renin production during the period of exchange transfusion and as independent variables the weight, postnatal age, basal PRA of the newborn, donor's PRA, and exchange rate. Allowing for the dilution caused by the donor's blood, hyperproduction of renin occurred in all cases. All these variables influenced, in various directions, the rate of renin release but the rate of exchange appears to be the most important factor in the activation of the renin-angiotensin system (multiple correlation coefficient = 0.774; F-value for analysis of variance = 16.404; standard error of estimate = 0.078; t = 4.050; $P < 0.01$).

Familial neurodegenerative disorder associated with raised urinary VMA

Sir,

The belief held by Young and Hosking (*Archives*, 1978, **53**, 682) that 'disturbances of catecholamine excretion have not been known to occur in children with a progressive neurological disorder or other neurological insult' is not true. Excessive urinary excretion of 4-hydroxy-3-methoxymandelic acid (HMMA) has been demonstrated in hydrocephalic infants with spina bifida (Barson and Hodge, 1971). It was felt from this study that a raised urinary HMMA reflected a persistently raised intracranial pressure, since it was not a feature of spina bifida alone or in cases where hydrocephalus was well controlled by a valve. It is likely that increased excretion of catecholamines is a nonspecific consequence of degenerating nerve tissue, whether this is in turn due to increased intracranial pressure or to an intrinsic neurological disorder.

Dr Hosking comments:

We are grateful to Dr Barson for drawing our attention to his important paper. It was remiss of us not to be aware of the data in that publication.

The raised levels of urinary HMMA seen in Drs Barson and Hodge's papers are most likely nonspecific as Dr Barson suggests. Similar increases are seen from time to time in a number of 'stress' situations. However, in our patient there was not only biochemical evidence of impaired catecholamine metabolism or excretion, but also clinical features apparently related directly to this abnormality. It is for this reason we suspect our patient's disordered metabolism was rather more specific.

Peripheral pulmonary artery stenosis

Sir,

The observation by Salisbury and Keeling (*Archives*, 1978, **53**, 428) of polypoid lesions in the peripheral pulmonary arteries of an infant, recalls a controversy that was resolved over 20 years ago. Originally described in systemic arteries by Bucciante in 1945 and later by many others, these structures became known as 'pedunculated nodules' or 'polypoid cushions' and were interpreted as flow regulation mechanisms. Later studies

(Wagenvoort and Planten, 1954; Staubesand, 1955) produced morphological evidence that they were artefacts and that they resulted from invaginations of the arterial wall when tissues are stretched and then cut. This may happen during surgery as well as at necropsy. Moffat (1956) produced these changes, which are identical with those described by Salisbury and Keeling, experimentally.

As for the pulmonary vasculature, in our experience they are found particularly often in the thick-walled pulmonary arteries of newborn infants and of patients with pulmonary hypertension of whatever cause (Wagenvoort *et al.*, 1964), while in normal adult individuals they are usually limited to the elastic pulmonary arteries and do not occur in the thin-walled muscular arteries in which the tendency to invaginate is apparently much less.

Dr Keeling comments:

We are aware that vascular 'abnormalities' may be produced by the casual treatment of tissues. The lungs in this case were fixed before blocks were taken for histological examination and we note that Moffat (1956) was unable to produce vascular 'lesions' when tissues were treated in this way; nor were we, on re-examination of semiserial sections of the lungs, able to find evidence of local vessel damage, thus excluding reported causes of artefact.

Weaning very low birthweight infants from mechanical ventilation using intermittent mandatory ventilation and theophylline

Sir,

We would like to support the observations of Dr Barr (*Archives*, 1978, **53**, 598) who found that theophylline therapy facilitated the weaning of infants from mechanical ventilation when apnoea and bradycardia occurred at low IMV rates. We have used this combination therapy in 2 infants with hyaline membrane disease (1620 g, 32 weeks' gestation; 2000 g, 34 weeks' gestation). Theophylline serum concentrations were closely monitored, and all were in the therapeutic range (6 to 11 mg/l). Both infants were severely ill. Each had bilateral pneumothoraces requiring chest tube drainage. Both developed significant apnoea and bradycardia at IMV rates less than 5, necessitating increased ventilatory support primarily in the form of repeated bagging during apnoeic episodes. The infants had dramatic responses to treatment with theophylline, and we were able to extubate both infants within 48 hours.

We too believe that theophylline can aid in weaning infants from ventilators when apnoea and bradycardia occur at low IMV rates. Theophylline can be beneficial not only for low birthweight infants but also for those in whom rapid extubation or a reduction in mean intrathoracic pressure is desirable. Our infants with pneumothoraces are good examples, and others (such as those with pneumopericardium) come readily to mind.

Detection of phenylketonuria

Sir,

Guthrie testing is performed at this hospital on blood samples received from the whole of Scotland, from children aged 6 to 14 days (Stevenson and Kennedy, 1974). Samples are assayed for phenylalanine, tyrosine, methionine, leucine, and galactose, blood samples being collected by hospitals or health visitors as appropriate, and a check on samples received compared with the number of registered births by the district medical officer.

Theoretically, therefore, all children should be included in this national scheme; although in practice the percentage of children sampled varies from 93–99% (Clayton, 1976).

In a recent search for the PKU cards of children born in Glasgow of known birth dates for another purpose, a surprising number of samples had either never been received by the hospital, or had not been taken within the recommended time of 6 to 14 days. Of 1000 sequential samples received from the Glasgow area during 4 weeks in 1977, in 4.2% of cases the child was 6 days old when the specimen was assayed, and must therefore have been less than 6 days old when the sample was taken. 93.8% of samples were taken at an 'acceptable' age of 7 to 21 days old; but in the remaining 2% of cases, the child was over 3 weeks old before the test was done; in 0.8% of cases, representing 100 samples per year in Glasgow, or 700 in Scotland, the child was more than 2 months—in some cases, as much as 7 months old.

Obviously in these cases the value of the test is much reduced, with the possibility that permanent brain damage would already have occurred before it was performed. This has two consequences—firstly, doctors who are working with sick young children should be aware that they may not have had inborn metabolic errors excluded by the National Screening Programme; secondly, if neonatal screening is to be extended to other conditions of personal or economic importance, such as hypothyroidism or lead poisoning, a truly fail-safe and universal screening programme would be needed, if it is to justify its cost.

Early onset of homozygous β^{0} thalassaemia associated with neonatal jaundice

Sir,

I read with interest the paper by Furbetta *et al.* on this subject (*Archives*, 1978, **53**, 250). Although they stated that 'all other common causes of neonatal jaundice had been excluded', the ABO set-up (blood group of baby A and the mother O) which is the most common cause of jaundice in the newborn, was present. In ABO incompatibility, the direct Coombs's test is usually negative. Therefore this possibility should be ruled out before ascribing the neonatal jaundice to thalassaemia.

I should also like to add that among our 90 patients with thalassaemia major (until 1970) pallor and distended abdomen were noticed at birth in two, at 17 days of age in one, at 20 days in one, at 30 days in two, and at about 40 days in two; the observation of splenomegaly as early as 17 days of age in one, might indicate that Cooley's anaemia in this area becomes symptomatic very early as stressed by the authors.

Ankara, Turkey

Professor Cao comments:

The letter from Prof. S. Ozsoylu raises the possibility that the neonatal jaundice could have been due to ABO incompatibility.

However there was evidence of a moderate haemolytic process with Hb level of 13 g/dl in the 5th day, and the jaundice was first noted on the 3rd day, while in ABO incompatibility there is usually little or no evidence of a haemolytic process, and hyperbilirubinaemia appears usually within 24 hours of birth. Moreover, microspherocytosis, a prominent feature of ABO haemolytic disease, was absent.

The direct Coombs's test on the infant's erythrocytes was negative, while in our laboratory, as in others, a weakly positive reaction in ABO haemolytic disease is common. Finally when there is ABO incompatibility it is our custom to test the eluate from the erythrocytes of the affected newborn with A (or B) adult cell. This reaction was negative, and not strongly positive as found usually in ABO haemolytic disease. ABO haemolytic disease cannot be ruled out with certainty in this case but the evidence makes this diagnosis highly improbable.

Prof. Ozsoylu comments that in the population under his care Cooley's anaemia often presented early. In the last year we diagnosed 80 new cases of Cooley's anaemia due to homozygous β^{0}-thalassaemia. An early presentation with criteria such as symptomatic anaemia (Hb <7–8 g/dl) at 75-90 days was observed in 30% of cases, but the severe anaemia (Hb <6 g/dl) at 60 days as seen in our patient was rather uncommon. Splenomegaly in cases with earlier presentation is an unusual feature in this area. The age and clinical findings at presentation in Cooley's anaemia varies in different ethnic groups. This may be due to the genetic heterogeneity of the disease and different environmental conditions.

Successful restoration of immunity in the DiGeorge syndrome with fetal thymic epithelial transplant

Sir,

I read with interest the paper by Thong *et al.* on this subject (*Archives*, 1978, **53**, 580). The authors stated that correction of the hypocalcaemia was achieved by the use of

AT10 (vitamin D2); in which AT10 was considered as equivalent to vitamin D2. AT10 (dihydrotachysterol) is quite different from vitamin D2 which is ergocalciferol. Although both compounds, after their hydroxylation in the liver and kidney would be effective on serum calcium levels, they differ in that AT10 may be rachitogenic in long usage but vitamin D is the compound recommended for the prevention and treatment of rickets.

Sinasi Ozsoylu
Hacettepe University Children's Medical Center,
Hacettepe Çocuk Hastanesi,
Ankara, Turkey

Drs Thong and Robertson comment:

We thank Professor Ozsoylu for his correction of our error. AT10 (dihydrotachysterol) is a reduction product of vitamin D and differs from vitamin D in the geometrical configuration of the A ring. This product has been used in the treatment of hypoparathyroidism for many years, and is preferred to calciferol by some because of its more rapid onset of biological activity and its more rapid excretion (Root and Harrison, 1976). We have seen no evidence of a rachitogenic effects in patients with hypoparathyroidism treated with either dihydrotachysterol or calciferol, nor have we seen such a report in the literature.

Perhaps Professor Ozsoylu's concern is based on the *in vitro* work of Trummel *et al.* (1971) and Reynolds *et al.* (1973) who showed a direct effect of both dihydrotachysterol and its 25-hydroxylated metabolite, 25-hydroxy-dihydrotachysterol on bone resorption in culture, which was greater than the effect of 25 hydroxycholecalciferol.

Both calciferol and dihydrotachysterol have been used effectively in the long-term management of hypoparathyroidism. Since, in the absence of parathyroid hormone, the production of the most active form of vitamin D, 1, 25-hyhidroxycholecalciferol is impaired, a more rational form of therapy would be this product or its synthetic analogue, 1α-hydroxycholecalciferol which have been shown to be effective. These products are not yet generally available (Russell *et al.*, 1974).

Book review

Pediatric Urologic Surgery. Edited by H. B. Eckstein, R. Hohenfellner, and D. I. Williams. (Pp. 533; illustrated + tables. £66.25 hardback.) Holt-Saunders: Eastbourne.

This surely is one of the finest operative texts yet produced and it will remain for some decades the most comprehensive and authoritative guide for all those tempted to operate on the urological problems of children. The timing of the production of this beautifully produced book is excellent as it coincides appropriately with the retirement from active paediatric urological practice of the senior author, Innes Williams, who has done more than anyone for this subject. Furthermore, it is only in the last year or two that techniques of this rapidly expanding specialty have become standardised although where there are still considerable controversies, as, for example with hypospadias, the book provides good coverage of many different techniques. Many operations such as penile lengthening and paediatric transplantation are not easily found elsewhere. Although the more complicated procedures in paediatric urology should not be performed by those who have not had adequate training in both urology and paediatric surgery, here at least is advice on how to perform safely virtually all operations one is likely to encounter.

The illustrations must be singled out for their excellence and it is pleasing to see the radiologists and anaesthetists writing as part of the team. Here is a book by internationally renowned experts that although expensive, as are all such good books, will be a prize possession for all those interested in this subject.

R. WHITTAKER

Shorter notice

Major Mental Handicap: Methods an Costs of Prevention. Ciba Foundatio Symposium 59 (new series). (Pp. 226 illustrated + tables. US $23.00 hardback Excerpta Medica: Amsterdam.

A Ciba symposium held in London i November 1977 with contributions from USA, Canada, France, Sweden W. Germany, Switzerland, Finlan besides the UK. The recent strikin improvement in the infant mortality i France, thought to be a consequence o the active measures initiated by th government, provided no doubt a mai impetus for the idea of 'cost-effectivenes being applied to perinatal work. Th final chapter by Chapalain of Par describing French experiences evaluating cost-benefit is thus particular worth while.

Hypothalamic and Pituitary Hormones

The Proceedings of a Symposium organised by the Association of Clinical Pathologists

Edited by G. K. McGowan and G. Walters

CONTENTS

Editors' foreword ● Anatomy of the hypothalamus and pituitary gland ● Pituitary and hypothalamic physiology ● Relationships of structure with function of the gonadotrophins ● Purification of anterior pituitary and hypothalamic hormones ● Cytochemical methods of hormone assay ● Secretion of hypothalamic and pituitary hormones by non-endocrine tumours ● Secretion of pituitary-like peptides by the human placenta ● Disorders of prolactin secretion ● Disorders of gonadotrophin secretion ● Gonadotrophin-releasing hormone ● Thyrotrophin-releasing hormone in clinical practice ● Therapeutic use of human growth hormone ● Management of acromegaly ● The posterior pituitary and diabetes insipidus

Obesity in Childhood

Proceedings of the Serono Symposia, Volume 7

edited by

E. Cacciari, Z. Laron and S. Raiti

August 1978, 248 pp.
£10.40
0.12.154150.9

Obesity is one of the greatest health problems in wealthy, developed countries. The purpose of this symposium on Obesity in Childhood was to re-examine some recurrent topics, such as long-range therapy and the psychological problems of the obese child: both the practising physician and the researcher concerned with obesity will find useful material here.

STATISTICS AT SQUARE ONE

by T. D. V. SWINSCOW

from the British Medical Journal

The statistical testing of data is indispensable in many types of medical investigation and a help on countless occasions in clinical practice. This book provides step-by-step instruction. Subjects covered include standard deviation, χ^2 tests, t tests, non-parametric tests, and correlation. The book includes sections on Fisher's exact probability test and rank correlation not published in the *B.M.J.* series. Methods specially adapted to pocket calculators.

"The ability to put symbols in sequence may well be one of the greatest advances in man's development . . . This excellent and attractive volume will give you an idea into which category an article or projected article fits. The ink you save may be your own. It is superb value."
O'Donnell, Barry, *British Medical Journal*, 1977, 1, 451.

". . . this gem of a practical booklet squeezes the essence of biostatistics into 75 well-written, well-organized pages. Newcomers to the field will like the way obscure concepts are clarified; experts will find the book valuable as a teaching aid."
de Jong, Rudolph H., *J.A.M.A.*, 1977, 237, 1874

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42,** 109; 1973, **48,** 751).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged.
(11) References in the text. Papers with one or two authors: name author(s) on each occasion the paper is cited with year of publication in parentheses. Papers with more than two authors: use—*et al.* in each citation.
(12) References to be listed alphabetically with full title of article or book; title of journal to be given in full, first *and* last page numbers of journal articles to be given.
(13) Summary to be typed on a separate sheet; and it should say what was done, and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood,* B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate from January 1979 will be £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

COPYRIGHT © 1979 by *Archives of Disease in Childhood.* This publication is copyright under the Berne Convention and the International Copyright Convention. All rights reserved. Apart from any relaxations permitted under national copyright laws, no part of this publication may be reproduced, stored in a retrieval system, or transmitted in any form or by any means without the prior permission of the copyright owners. Permission is not, however, required to copy abstracts of papers or of articles on condition that a full reference to the source is shown. Multiple copying of the contents of the publication without permission is always illegal.

Reduced Subscription Rates for Junior Hospital Doctors Residents and Interns...

from January 1 1979

Archives of Disease in Childhood

will be available to junior doctors in all parts of the world for a maximum of four consecutive years at REDUCED Annual Subscription Rates. (Thereafter, or when reaching consultant status this special offer will no longer apply.) The following subscription rates apply for the twelve issues published in 1979.

Inland £17.00

Overseas US$40.00

(The full rates are: Inland £28.00; Overseas US$65.50)

The opportunity to subscribe to this journal of international authority and repute at a substantially reduced subscription rate is one not to be missed by junior doctors seeking to specialise in paediatrics.

Please complete the adjacent order form and send for your subscription NOW.

Further order forms can be supplied on request.

The Relationship of Amniotic Membrane 11-Oxidoreductase Activity to Lung Maturation in the Human Fetus 957

A. K. Tanswell and B. T. Smith (Kingston, Ontario, Canada)

The findings demonstrate that in pregnancies where the fetus is destined to develop respiratory distress syndrome after delivery, the amniotic membranes are defective in their ability to produce cortisol, resulting in a possible reduction in the amount of cortisol available to the fetal lung during maturation *in utero*.

Cellular and Humoral Immunity in Cartilage-Hair Hypoplasia 961

M. Virolainen, E. Savilahti, I. Kaitila, and J. Perheentupa (Helsinki, Finland)

In an unselected series of 28 subjects with cartilage-hair hypoplasia, almost all subjects had subnormal responses in tests of cellular immunity, although most of them had no apparent unusual susceptibility to infections. This feature was a more constant feature of the syndrome than the hair abnormality.

Salivary Amylase in Cystic Fibrosis: A Marker of Disordered Autonomic Function 967

G. P. Davidson, A. Koheil, and G. G. Forstner (Toronto, Ontario, Canada)

To determine whether an increased salivary isoenzyme activity might be present in cystic fibrosis, these scientists examined total serum amylase and isoenzyme patterns from a series of patients, including cystic fibrosis (CF) patients with and without steatorrhea, patients with exocrine pancreatic insufficiency without CF (Shwachman's syndrome), and a control group who had neither CF nor pancreatic insufficiency.

The Effect of Racemic, D-Propranolol, L-Propranolol, and Practolol on the Response to Cold by the Newborn Rabbit 971

I. Dober, V. Jaszai, T. Heim, and R. D. G. Milner (Pecs, Hungary, Toronto, Canada, and Sheffield, England)

In this investigation the newborn rabbit has been used as a model to investigate the effects of propranolol, the isomers of propranolol, and practolol on the response to cold exposure.

Fetomaternal Potassium Relations in the Rat on the Twentieth Day of Gestation. II. Effects of Maternal Hypocalemia 977

A. G. Fantel (Seattle, Washington)

A study of potassium homeostatis during maternal hyypokalemia was undertaken in potassium-deficient rats on the 20th day of gestation.

Plasma 25-Hydroxyvitamin D in Familial Hypercholesterolemic Children Receiving Colestipol Resin 980

R. C. Tsang, M. S. Roginsky, M. J. Mellies, and C. J. Glueck (Cincinnati, Ohio)

The effects of colestipol, a new synthetic organic bile sequestrant polymer (U26-597A), on vitamin D metabolism have been assessed in children with familial hypercholesterolemia over a 2-year period.

Pulmonary Diffusing Capacity in Lambs During the Early Neonatal Period 983

J. M. Bissonnette, W. H. Drummond, W. K. Wickham, and J. Z. Cronan (Portland, Oregon)

When a rebreathing method to measure pulmonary diffusing capacity in neonatal lambs was employed, a significant increase in diffusing capacity was found to take place in the first day of life.

Distortions in Fetal Growth Standards 987

R. L. Naeye and J. B. Dixon (Hershey, Pennyslvania)

The findings of the present studies indicate that widely used fetal growth standards appear to include measurements from both growth-retarded neonates and from neonates older than their calculated gestational ages.

Maturation of *p*-Aminohippuric Acid Transport in the Developing Rabbit Kidney: Interrelationships of the Individual Components 992

B. R. Cole. J. T. Brocklebank, R. G. Capps, B. N. Murray, and A. M. Robson (St. Louis, Missouri)

This investigation was undertaken to examine systematically the contribution of the individual cellular mechanisms to the reduction on aryl acid excretion in the immature rabbit kidney with *p*-aminohippuric acid being used as the test aryl acid.

Abnormal Colonization of Neonates in an Intensive Care Unit: Means of Identifying Neonates at Risk of Infection 998

K. Sprunt, G. Leidy, and W. Redman (New York, New York)

Results of these studies indicate that serial throat cultures permit selection of the group of Intensive Care Unit neonates at greatest risk of infection and indicate the probable organism from which they are at risk.

Infa-Care Neonatal Products

NEW...From Puritan-Bennett

The family of Infa-Care neonatal products includes radiant heat incubators and physiological monitoring equipment. Its flexible, modular design allows you to tailor the equipment system to best meet the needs of the patient. Either a closed or open mode of radiant heating may be selected.
Also, you may choose from three bassinets and from any or all of the monitoring modules for ECG/heart rate, respiration rate and oxygen concentrations.
This flexibility is available in either the Model 1000 or Model 2000 Infa-Care Radiant Heat Incubator.
For more information on our family of products, contact your nearest Puritan-Bennett distributor for a demonstration.

Striatal degeneration in childhood

MAGDA ERDOHAZI AND P. MARSHALL

The Hospital for Sick Children, London

SUMMARY The clinical features, and the radiological and neuropathological findings of 3 unrelated children with striatal degeneration are presented. In one case the father had recently developed choreiform movements while in the other two the family history was negative for neurological disorders. Two patients had juvenile onset of psychiatric symptoms, seizures, and rigidity. The 3rd child presented with focal seizures at 9 weeks of age. The neuropathological findings are virtually identical in all 3 cases. The classification of striatal degeneration in childhood is discussed.

Isolated degeneration of the striate body in childhood is rare and constitutes a diagnostic problem. Patients with juvenile Huntington's disease demonstrate striatal degeneration but the lesion is not usually restricted to that structure. Cases with striatal necrosis have also been described. Three unrelated children with progressive degeneration of the striate body are reported.

Case reports

Case 1. This girl was the first child of unrelated healthy white parents. She was born at term after a normal pregnancy, labour, and delivery and weighed 3·02 kg at birth. There was no family history of neurological disorder, but the father had been adopted and details of his family's medical history are not known. The father remained in good health until about one year after his daughter's death when, at 30 years, he gradually developed choreiform movements. The patient's younger sister, now aged 11, remains in good health. Up to age 5 years, the only abnormalities noted in the patient were a mild dysarthria and a tendency to walk on her toes. At age 5 years she was seen by a psychiatrist because of occasional incontinence and the development of disturbed behaviour characterised by sudden outbursts of crying without obvious reason. Physical examination at that time showed left internal strabismus, slight increase in muscle tone in all extremities, and mild incoordination. Her full scale IQ by the Stanford-Binet test was 92. At age 7½ years she had her first generalised convulsion but no more occurred until a year later. Meanwhile, a slow deterioration in her mental capacity became evident and at age 8 years her IQ had dropped to 54.

She was first seen at The Hospital for Sick Children at age 9 years. During the previous year she had had increasingly severe generalised, akinetic, and myoclonic seizures which responded poorly to a variety of anticonvulsant medications. On examination she was alert, co-operative, but obviously mentally retarded. Her head circumference (49 cm) and her height were at the 3rd centile. She had an impassive facies and mild ptosis of the left eyelid. There was difficulty in initiating movements and postural control was poor. She had a fine resting tremor and an unsteady tip-toe gait. Generalised rigidity was noted and the tendon jerks were brisk. The plantar responses were flexor.

An electroencephalogram demonstrated multifocal spike discharges, particularly on the left. Electroretinography and visual evoked responses were normal. Nerve conduction studies were normal. Although an electromyogram was suggestive of myopathy, a muscle biopsy was within normal limits. Computerised tomography of the head demonstrated enlargement of the lateral ventricles, particularly anteriorly (Fig. 1). Routine investigations of blood and urine were normal as were serum electrolytes and liver function studies. Serum copper and caeruloplasmin levels were normal. There was no increase in blood pyruvate or lactate. Assays for white blood cell β-galactosidase, arylsulphatase A, and hexosaminidase A and B activity were within the normal range. CSF examination showed no abnormality.

After discharge from hospital, our patient's seizures were better controlled but the tremor and rigidity were increasing. She was admitted to the local

hospital at age 9½ years because she had become too difficult to manage at home. She died 3 months later after further neurological deterioration.

Necropsy (*Dr R. Salm*)
The body was rather thin. No lesions were found except in the CNS.

The brain was reduced in size, the total weight being 1070 g; the cerebellum and brain stem accounted for 154 g. (The average weight of normal brain is 1290 g for this age.) No morphological abnormality was noted externally but coronal sectioning showed enlargement of the lateral ventricles which was more pronounced anteriorly at the level of the striate body. The caudate nucleus and the putamen were shrunken on both sides (Fig. 2). The shrinkage of the caudate nucleus was severe along its entire length, while that of the putamen appeared less marked more posteriorly. There was slight shrinkage of the thalamus and the third ventricle was enlarged (Fig. 3).

Both the caudate nucleus and the putamen showed great loss of neurons, the small neurons being mainly affected. The lesion was increasingly severe caudally. The loss of neurons was accompanied by moderate astrocytic proliferation (Fig. 4). The glial fibre formation was sparse (Fig. 5). Sudanophil or PAS-positive material was not demonstrated in the caudate nucleus or putamen. In sections stained for myelin and axons it was obvious that there was marked loss of the caudato-putaminal and putamino-pallidal fibres (Fig. 6). The globus pallidus and the thalamus showed no neuronal loss or gliosis but the myelin sheaths were weakly staining and there was some loss of axons. Patchy loss of nerve fibres accompanied by demyelination was also present in

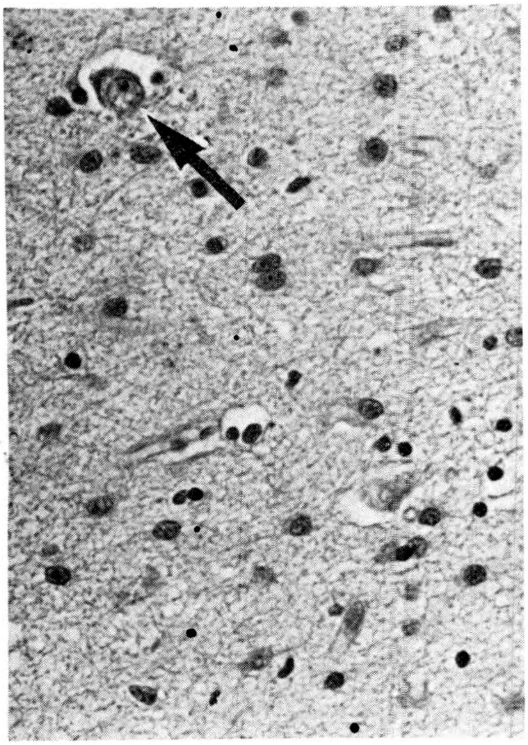

Fig. 4 *Microphotograph of putamen showing a single neuron (arrow) in a field of proliferating astrocytes. H & E ×400.*

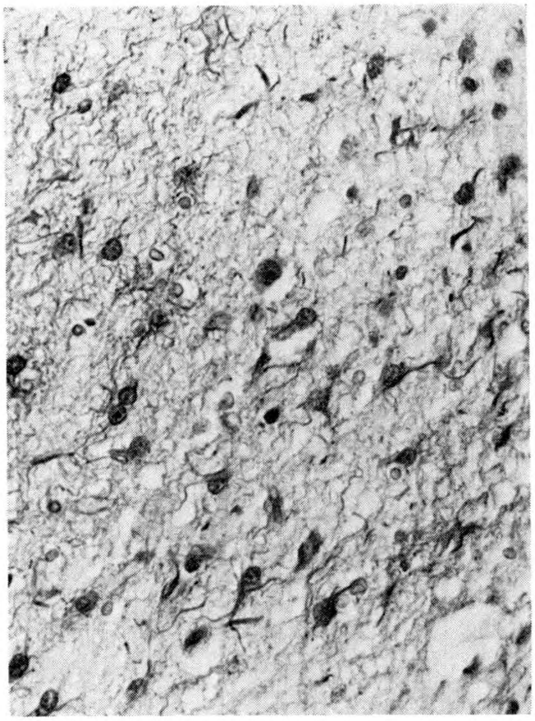

Fig. 5 *Microphotograph of putamen showing astrocytic nuclei with spare glial fibre formation. Holzer ×400.*

the internal capsule. The claustrum, substantia nigra, subthalmic nucleus, red nucleus, and amygdaloid nucleus were intact.

The cerebral cortex showed good preservation in all regions except in the Ammon's horn where there was some neuronal loss and gliosis in the Sommer's sector and endplate. The centrum semiovale and corpus callosum were normally myelinated. The only changes in the brain stem were in the inferior olives. The spinal cord was not available for examination.

The cerebellar cortex showed severe diffuse loss of Purkinje and granule cells with prominent gliosis in all parts. Patchy neuronal loss was observed in the dentate nucleus and the white matter was somewhat pale on myelin staining. The inferior olives showed slight loss of neurons.

Case 2. This baby girl was the 2nd child of non-consanguineous white parents. There is an elder sister, one year older, who remains well. The father died at age 28 years of carcinoma of the stomach. There is no family history of degenerative neurological disease. The patient weighed 3·6 kg at birth and was 2 weeks postmature. Pregnancy, labour, and delivery were otherwise normal. Growth and developmental milestones were normal until 3½ years when she was noted to have a fine tremor of the hands. During the next 2 years she developed increasing clumsiness of gait and slurring of speech. At age 5½ years behavioural problems became evident. She had violent swings of mood with screaming at night and outbursts of violence towards her sister followed by withdrawal and apathy. She was admitted to The Hospital for Sick Children for evaluation.

On examination she was distractible and generally behaved in an immature manner. Her head circumference approximated the 50th centile (50 cm). She had a fine action tremor and was clumsy in manipulating small objects. Her gait was clumsy and awkward. The deep tendon reflexes were brisk. The plantar responses were extensor. Her verbal IQ score was 85 and her performance IQ score was 70 on the Wechsler scale. The neurological examination was otherwise normal. An electroencephalogram demonstrated multifocal spike discharges with variable localisation. During the next year she

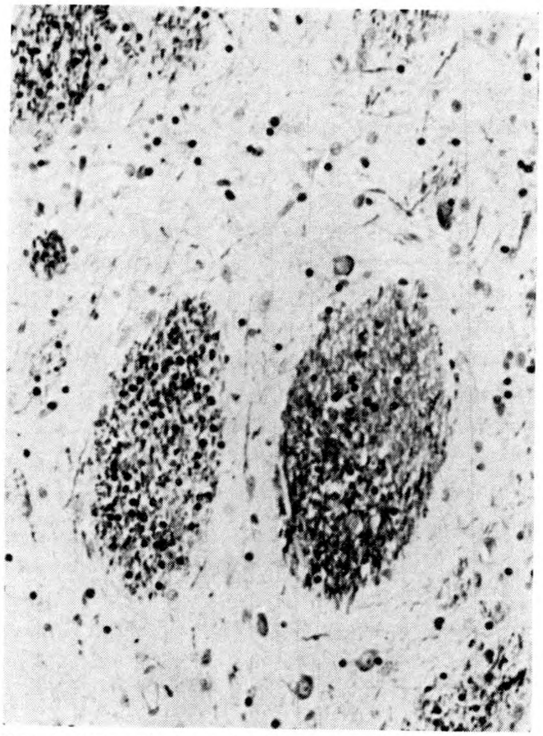

Fig. 6 *Microphotograph of putamino-pallidal bundles showing partial demyelination. Luxol fast blue and cresyl violet. ×240.*

continued to deteriorate. She began to have brief drop attacks and her educational progress ceased. By 6½ years she had developed cogwheel rigidity of all extremities. She was readmitted to hospital. Her head circumference was 52 cm. An air encephalogram was normal. Examination of the CSF showed no abnormality. Blood and urinary amino-acid pattern was normal. Serum copper and copper oxidase levels were normal. At this time she had her first generalised convulsion. Thereafter she had frequent seizures which were generalised, akinetic, or myoclonic in type. Anticonvulsants only partially controlled the convulsions and a course of ACTH did not result in clinical improvement. A trial of benzhexol (Artane) did not alter the rigidity. During the next 18 months repeated admissions were necessary to control her seizures. When admitted at 8 years, she was severely demented and could say only a few intelligible words. She seemed to suffer from terrifying hallucinations and declared she saw insects in her bedclothes and hair. Her head circumference was 51 cm. She was rigid and lay in a 'catatonic' posture with a face lacking any expression. Any voluntary movement of the upper extremities was hampered by severe action tremor. She had difficulty in swallowing which necessitated feeding through a nasogastric tube. All reflexes were brisk. Sustained ankle clonus was present. The plantar responses were extensor. The fundi were normal and there was no abnormality of eye movements. She died of bronchopneumonia at age 8¼ years.

Necropsy

The body was thin with slight flexion contractures of the elbows and knees. The lungs showed bronchopneumonia. No other abnormalities were found except in the CNS.

The brain was reduced in size, the total weight being 1120 g; the cerebellum and brain stem accounted for 133 g. (The average normal brain weight for this age is 1273 g.) No morphological abnormality was noted externally but coronal sectioning showed enlarged lateral ventricles. The enlargement was more pronounced anteriorly owing to the shrinkage of the striate bodies (Fig. 7).

The caudate nucleus and putamen showed moderate loss of nerve cells, the small neurons being mainly affected. The neuronal loss was accompanied by marked astrocytic proliferation and slight fibrous gliosis. The caudate nucleus was fairly uniformly affected at every level while in the putamen the damage was greater in the lateral than in the medial portions. The caudato-putaminal and putamino-pallidal bundles showed severe loss of nerve fibres and the myelin sheaths were poorly stained. The globus pallidus showed slight pallor of myelin. No changes were present in the hypothalamus, thalamus, claustrum, substantia nigra, or amygdaloid nucleus.

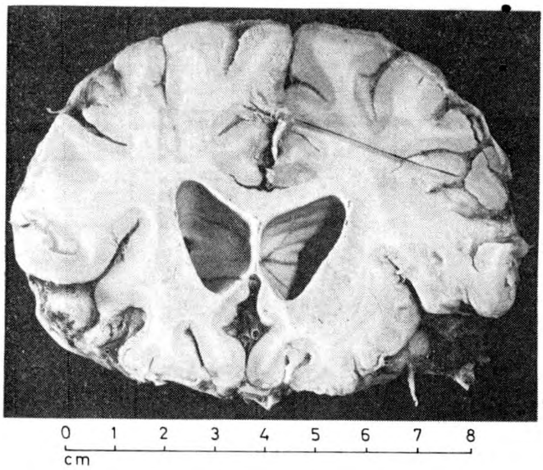

Fig. 7 *Coronal slice of the brain. Note marked shrinkage of the striate body.*

No abnormality was detected in the cerebral cortex or centrum semiovale.

The cerebellar cortex showed moderate loss of Purkinje and granule cells. The inferior olives showed slight loss of nerve cells but otherwise the brain stem was normal. The spinal cord was normal at all levels.

Case 3. This boy was the second child of unrelated white parents. An older brother and a younger sister remain in good health. There is no family history of neurological disease. Pregnancy was complicated by bleeding at 4 months which necessitated hospital observation. Fetal movements may have been diminished. The delivery at term was uneventful. The birthweight was 3·8 kg. He was noted to smile and follow visually at 6 weeks, and he was sitting without support at 3½ months. However, at 9 weeks he had, on the same day, 5 left-sided seizures each lasting 10 min, unassociated with fever. He was admitted to a local hospital where an electroencephalogram suggested a right-sided abnormality with a background of generalised slowing. Approximately one month later, 4 similar attacks occurred. Phenobarbitone was administered but 24 hours later the child had a generalised seizure lasting 20 min. Diphenylhydantoin was added to the treatment but continued left-sided and generalised convulsions necessitated another hospital admission at 4 months of age. Examination at that time showed a rather pale, visually attentive infant who reached for objects without difficulty. His head circumference was at the 50th centile (42 cm). He had normal head control and vocalisation for his age. Hearing appeared intact. The other cranial nerves were also normal. The child preferred to use the right hand. The muscle tone was normal The deep tendon reflexes were slightly brisker on the left. The plantar responses were equivocal. Laboratory investigations included a normal blood count, urine analysis, and serum electrolytes. Blood and urine amino and organic acid pattern was normal. Screening tests for congenital infections including rubella, toxoplasmosis, and cytomegalic inclusion disease were negative. The CSF was normal. An electroencephalogram demonstrated multifocal spike discharges, especially on the right. An air encephalogram was performed which suggested cerebral atrophy.

Continued seizures precipitated readmission at 7 months. His head circumference was 44 cm. The neurological findings were unchanged except that his response to auditory stimuli was less acute than at the previous examination at 4 months. His course continued to be marked by periods of poor control of the seizures.

During the next year he developed complex choreoathetotic movements of all extremities. There was marked hypotonia although the tendon jerks were brisk. The child was developmentally retarded at the 4 months level. His condition remained static until he died at age 2¾ years.

Necropsy

The body was well covered and there was fine hair over the neck, back, arms, and thighs. The head was small, head circumference 45 cm. There was terminal bronchopneumonia. No abnormality was detected in any organ except the CNS.

The brain was reduced in size, the total weight being 810 g, the cerebellum and brain stem accounting for 90 g. (The average weight of normal brain is 1140 g for this age.) No morphological abnormality was noted externally but coronal sectioning showed enlargement of the lateral ventricles which was most pronounced anteriorly. The caudate nucleus was shrunken along its entire length while the putamen appeared to be of normal size (Fig. 8).

Marked loss of neurons was observed in the caudate nucleus, the small nerve cells being affected more than the large ones. The degeneration was accompanied by prominent astrocytic gliosis but only little fibrillary reaction. The process was

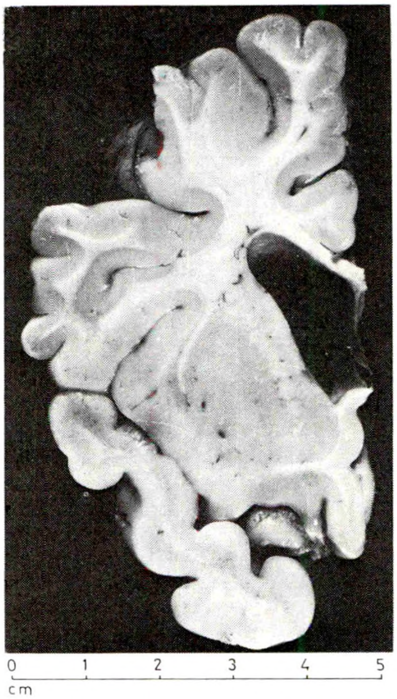

Fig. 8 *Coronal slice of left hemisphere. Note marked shrinkage of the caudate nucleus.*

increasingly severe more caudally. There were also a few microscopical foci of spongy appearance. The putamen on either side showed less marked loss of neurons, but there was obvious proliferation of astrocytes in the dorsal regions. Loss of nerve fibres was noted in the caudato-putaminal bundles. No changes were seen in the thalamus, subthalamic nucleus, globus pallidus, substantia nigra, or mammillary body. The Ammon's horn showed marked neuronal loss and gliosis throughout. The remainder of the cerebral cortex was well preserved. The centrum semiovale was normally myelinated.

There was severe loss of Purkinje and granule cells in the cerebellar cortex with prominent gliosis. The white matter of the folia showed pallor on myelin staining. Slight loss of nerve cells was apparent in the inferior olives. The pons showed a few microscopical foci of recent haemorrhage. There was no abnormality in the spinal cord.

Discussion

The outstanding pathological feature of the 3 cases presented is bilateral striatal degeneration. The histological picture bears the hallmarks of a chronic process—i.e. total absence of a mesodermal reaction and breakdown material in spite of the obvious neuronal loss and astrocytic proliferation.

Degeneration of the striatum is the characteristic lesion in Huntington's disease (Campbell *et al.*, 1961; Jervis, 1963; Markham and Knox, 1965; Byers and Dodge, 1967; Byers *et al.*, 1973). However, Byers *et al.* (1973) reviewing the neuropathological findings in 14 children with Huntington's disease, noted that in addition to the striatal lesion, virtually all reported cases also showed degeneration of the globus pallidus and the cerebral cortex albeit to a less severe degree than that of the striate body. In their own 4 cases which were extensively studied similar damage was detected in the thalamus, pontine tegmentum, vestibular nuclei, and the cerebellum.

Roessmann and Schwartz (1973) described 2 brothers with a subacute progressive neurological syndrome that was characterised by onset in infancy, psychomotor retardation, and rigidity. Pathological examination showed marked neuronal loss in the caudate nucleus and putamen, accompanied by moderate astrocytic proliferation. The rest of the brain was reported as normal.

An apparently distinct entity of necrosis of the striate body has been reported by several authors (Marinesco and Draganesco, 1929; Hawke and Donohue, 1950; Miyoshi *et al.*, 1969). The neurological symptoms began after a febrile illness in childhood. The clinical features included alteration of consciousness and abnormal muscle tone with involuntary movements and, occasionally, myoclonic seizures. Naked eye examination of the brains disclosed softening of the caudate nucleus and the putamen. Microscopically the softened areas were necrotic with brisk mesodermal reaction. Some of the cases were familial.

Verhaart (1938) described striatal necrosis in a series of patients who also showed similar lesions in other regions of the brain, particularly in the basal ganglia and brain stem. It was suggested (Friede, 1975) that his cases may represent an early description of Leigh's subacute necrotising encephalomyelopathy.

The nosological classification of our cases poses considerable difficulty. Pathologically all 3 showed progressive degeneration of the striate body. In Cases 1 and 2 both the caudate nucleus and putamen were severely affected, while in Case 3 only the caudate nucleus showed severe degeneration with a less pronounced lesion in the putamen. Furthermore, the clinical course of Case 3 differed from the others. Cases 1 and 2 were remarkably similar in the juvenile onset of psychiatric symptoms, seizures, dementia, tremor, and rigidity. Case 3, on the other hand, presented at 9 weeks with seizures that were refractory to anticonvulsant therapy. His clinical course was characterised by psychomotor retardation, hypotonia, and choreoathetosis in addition to severe seizures. He died before his 3rd birthday.

Cases 1 and 2 bear notable similarity to Huntington's disease in their clinical course. However, only Case 1 has a positive family history in that her father developed chorea at age 30, six years after the onset of symptoms, and one year after the death of his daughter. In view of this history and the clinical course Case 1 is, in our opinion, a case of juvenile Huntington's disease, in spite of the fact that the neuropathological lesions in her case were more restricted than those in previous reports (Byers *et al.*, 1973). The pathological features of our cases are more similar to those described by Roessmann and Schwartz (1973). The only significant difference is in the cerebellum. However, we feel that the loss of Purkinje and granule cells in the cerebellar cortex may be secondary, caused either by the intractable seizures or anticonvulsant medication (Hoffman, 1958). This would be supported by the neuronal loss and gliosis in the Ammon's horn in Cases 1 and 3. The clinical presentation and course in Cases 1 and 2 were dissimilar from those of Roessmann and Schwartz. Case 3 was similar to their cases in age of onset but seizures, which were so prominent in our patient, were not noted in those of Roessmann and Schwartz. Our cases also differed in that there was no evidence of siblings being similarly affected.

While our Cases 1 and 2 bear clinical similarity to juvenile Huntington's disease with a positive family history in Case 1, the pathology in all 3 patients resembles more closely the cases of striatal degeneration reported by Roessmann and Schwartz. The diagnostic problem is whether all these cases represent a single disease of wide spectrum with the same biochemical defect or whether the clinical and pathological differences are significant and therefore there is more than one disease. The genetic implications make such a distinction important. Huntington's disease is an autosomal dominant disorder whereas the cases of Roessmann and Schwartz suggest an autosomal recessive pattern. The final classification of striatal degeneration has to await the determination of the underlying biochemical defect.

We thank Dr J. Wilson for his advice and permission to publish reports of his patients, and Dr B. E. Kendall for the interpretation of the CAT scan. The histological sections were done by Mrs Jenny A. Taylor, Mrs Jean M. Barron, and Mrs Jane M. Weir. The photographs were produced by Mr N. G. Le Page and Mr R. J. Lunnon.

We also thank Dr W. G. P. Mair for his advice.

Screening for cystic fibrosis in the newborn by meconium analysis

H. C. RYLEY, LYNNE M. NEALE, T. D. BROGAN, AND P. T. BRAY

Welsh National School of Medicine, Cardiff

SUMMARY During a 4-year routine screening programme for cystic fibrosis (CF) 15 464 specimens were examined for raised meconium albumin levels by a test strip method and by electroimmunoassay. The incidence of false-positive results was about 5 per 1000 specimens in either test. This could be reduced by 90% by determining the ratio of albumin : α-1-trypsin inhibitor (a ratio below 2·0 being considered as a negative result), and it could be reduced to zero by determining the ratio in subsequent faecal specimens. Three of 12 meconium specimens from infants with proved CF gave false-negative results in all 3 tests. The other 9 specimens had >100 mg albumin/g dry weight and albumin: α-1-trypsin inhibitor ratios of >3·0; in subsequent faecal specimens the ratios were over 4·0. 176 meconium specimens from elsewhere in the UK were examined and these included 23 from infants who were subsequently proved to have CF. Six of these 23 CF specimens gave false-negative results, the other 17 being strongly positive. The origins of meconium serum protein suggest that infants with CF in whom meconium gives false-negative results have normal pancreatic functions at birth. The specificity of current meconium tests therefore cannot be improved as they depend on pancreatic dysfunction.

The fact that the prognosis for infants with cystic fibrosis (CF) is improving is probably related to earlier diagnosis of the disease, thus enabling treatment to begin before the onset of irreversible pulmonary changes (Huang *et al.*, 1970; Shwachman *et al.*, 1970; Stern *et al.*, 1976; Orenstein *et al.*, 1977). With the exception of infants born with meconium ileus, the presence of CF in the newborn may not be suspected clinically for some time after birth and irreversible lung damage may have occurred (Warwick, 1969; Shwachman *et al.*, 1970). There is therefore a case for mass neonatal screening for CF in those countries where the incidence of the disease is high.

Although the detection of raised concentrations of ions in the sweat is the most specific and accurate test for CF, for technical reasons this approach is not at present suitable for mass screening (Committee for a Study for Evaluation of Testing for Cystic Fibrosis, 1976). Most neonatal screening tests for CF thus depend on the detection of a raised albumin content in meconium either by the semiquantitative test strip (Stephan *et al.*, 1975) or by other immunochemical methods (Kollberg and Hellsing, 1975; Ryley *et al.*, 1975; Schuttringer and Zinterhofer, 1978). The raised meconium albumin content most probably reflects a reduction in, or even absence of, pancreatic secretions containing proteolytic enzymes.

We report here the results from a 4-year study of CF screening by meconium analysis in which a comparison was made between the Boehringer Mannheim meconium test strip (BM-mec test) and the electroimmunoassay of albumin. The albumin: α-1-trypsin inhibitor (alb: α-1-TI) ratio both in meconium and in subsequent faecal specimens was also assessed for its ability to improve the specificity of screening.

Methods and materials

Collection of meconium and faeces. Meconium specimens were collected daily from the maternity units of the University Hospital of Wales, Cardiff, from December 1973 to November 1977 and from St David's Hospital, Cardiff, from April 1975 to November 1977. During the 4-year period of the study, meconium specimens from home births were sent to the laboratory via the Community

Department of Medical Microbiology, Welsh National School of Medicine, Cardiff
H. C. RYLEY, senior scientific officer
LYNNE M. NEALE, technician
T. D. BROGAN, consultant pathologist
P. T. BRAY, consultant paediatrician

Midwives Unit. Analysis of 15 464 specimens was carried out, of which 12 specimens were from infants with subsequently confirmed CF. Additional meconium specimens from 176 infants, 23 of whom were subsequently confirmed to have CF, were sent from other hospitals in the UK and were considered separately. Faecal specimens were analysed from 203 infants whose meconium gave a positive result with any test or from infants clinically suspected as having CF.

Collection of cord sera and amniotic fluid. Cord sera matched with the infants' meconium specimens were obtained during a routine screening investigation into α-1-trypsin inhibitor deficiency in the newborn. Amniotic fluid specimens were taken at the University Hospital of Wales, from each mother in whom the pregnancy was thought to carry a high risk of fetal abnormality. Specimens contaminated with blood or from babies in whom a congenital disorder was confirmed were not included in the results. All specimens were collected at an estimated gestation of 16–22 weeks.

Laboratory procedure for studying specimens. Meconium specimens were first tested with the BM mec-test (Boehringer Mannheim GmbH., Mannheim, Germany) and part of each specimen was transferred to a universal container for electroimmunoassay. A 4% wet weight suspension of the specimen in 0·9% sodium chloride was prepared by homogenising the specimen in saline with the aid of a 19 mm diameter Teflon pestle (A. H. Thomas, Philadelphia, USA) driven by a stirring motor at 2000 rev/min (Baird and Tatlock, Essex, UK) for about 10 seconds. A 4% wet weight suspension was approximately equivalent to a 1% dry weight suspension previously used (Ryley *et al.*, 1975). It was found unnecessary to remove the insoluble debris before analysing the protein content by electroimmunoassay. The rest of the specimen was freeze-dried and stored at 4°C for future reference. For purpose of comparison, albumin/g dry weight was estimated for all specimens in which albumin had been detected in the 4% wet weight suspension.

Faeces were not tested by the BM mec-test as the albumin content, even in specimens from infants with CF, was very low. On receipt of the specimen, a 16% wet weight suspension, approximately equivalent to a 4% dry weight suspension (Ryley *et al.*, 1976), was prepared in saline. The suspension was homogenised in a sealed universal container by a vortex mixer. The alb:α-1-TI ratio was determined for all faecal specimens.

BM mec-test for protein in meconium. Specimens were tested with the BM mec-test and the results classified as negative, possible positive, or positive (Ryley *et al.*, 1975).

Quantitative electroimmunoassay. Electroimmunoassay of albumin, α-1-TI, and α-1-CI in meconium and faeces was carried out as described (Ryley *et al.*, 1975, 1976). Protein concentrations in undiluted amniotic fluid and cord sera, diluted 1:20 with barbitone buffer were also estimated by electroimmunoassay.

Results

Comparison of the BM mec-test and electroimmunoassay for albumin. Five infants per 1000 passed meconium specimens that gave a positive or a possible positive result. 34 infants per 1000 passed meconium that contained more than 1 mg albumin/g dry weight and about 5 per 1000 specimens had values in excess of 20 mg/g dry weight. As over 20 mg albumin/g dry weight (5 mg/g wet weight) is usually taken as positive, the false-positive rate was similar in either test (Table 1).

When specimens from infants with CF were tested, 9 were positive and 3 negative in the BM mec-test. The 9 positive specimens all had levels in excess of 100 mg albumin/g dry weight with a mean value of

*Specimens routinely screened in Cardiff between November 1973 and October 1977.

313 ± 145 mg/g dry weight (110–490 mg/g dry weight). Two of the other 3 specimens had <1 mg albumin/g dry weight and the 3rd had 11 mg/g dry weight. Thus all 3 specimens gave false-negative results with both albumin tests (Table 1).

23 meconium specimens from infants with CF were also examined independently of the routine screening programme. 17 gave positive results with the BM mec-test and had >50 mg albumin/g dry weight with a mean value of 283 ± 138 mg/g dry weight (range 78–510 mg/g dry weight). One specimen gave a possible positive result with the BM mec-test and had 34 mg albumin/g dry weight. The other 5 specimens gave negative results with the BM mec-test and had 1·0–17·0 mg albumin/g dry weight.

Evaluation of the alb: α-1-TI ratio. An alb: α-1-TI ratio value was estimated for each specimen that contained >4 mg albumin/g dry weight and for each meconium specimen from an infant with CF, irrespective of albumin content (Table 2). Wherever possible, the ratio was subsequently estimated for faeces. A value of 2·0 was taken as the borderline value between positive and negative results (Ryley *et al.*, 1975). Two specimens contained <20 mg albumin/g dry weight but had ratios of over 2·0. One specimen was from an infant who died a few days after birth and was found at necropsy to have oesophageal atresia without a tracheo-oesophageal fistula. The other was from an infant previously described by us (Ryley *et al.*, 1975) in whom the ratio had been artificially high because the mother had ZZ α-1-TI deficiency. 65 specimens from infants without CF had >20 mg albumin/g dry weight and 9 of these also had a ratio of over 2·0. However the alb: α-1-TI ratios in the subsequent faecal specimens were not higher than 0·2 in any of the 9 infants. Eight of the 9 were premature with estimated gestation ages of between 27 and 33 weeks, and the specimen from the 9th infant was contaminated with blood. 10 other specimens appeared to be contaminated with blood but in none was the ratio above 2·0.

The 9 positive meconium specimens from infants with CF all had ratios of >2·0 with a mean value of 8·2 ± 5·3 (range 3·0–20·0). In all 7 follow-up faecal specimens, the ratio value was >4·0. The 3 negative meconium specimens from infants with CF also had ratios of <0·2; in follow-up studies, faeces from 2 infants gave ratios of 5·1 and 3·5. Faeces from the 3rd infant had a ratio of <0·1 but this child was receiving a pancreatic enzyme supplement to his diet.

18 specimens of meconium from CF infants outside the screening programme had >20 mg albumin/g dry weight and 17 had ratios >2·0 with a mean value of 7·0 ± 3·9 (range 3·0–16·0). The other specimen which had the lowest albumin content of the 18 (34 mg/g dry weight) had a ratio of 0·3.

Five specimens had a low albumin content, 4 had ratios of <0·2 and one, from an infant with meconium ileus, had a ratio of 2·1. In cases where follow-up studies on faeces were possible, all but one specimen had a ratio of >2·0.

In addition to the above, 3 faecal specimens were obtained from infants with CF in whom the meconium had not been screened at birth and all 3 specimens had ratios >3·0. Conversely no faecal specimen from infants in whom CF was initially suspected but not subsequently confirmed, gave ratios higher than 0·15.

False-negative results. Nine of the 35 meconium specimens from all infants with CF gave a false-negative result in at least one of the 3 tests (Table 3). Specimens 1–7 gave a negative result with the BM mec-test, albumin assay, and alb: α-1-TI ratio. Specimen 8 gave a borderline positive result with the test strip and albumin assay, but gave a negative ratio result. Specimen 9 gave negative test strip and albumin results, but a borderline positive ratio. CF was confirmed in Cases 1–8 by the infant having symptoms consistent with the disease and positive results to the sweat test. Case 9, born with meconium ileus, died soon after an operation; the diagnosis of

*Diagnosis of CF made on evidence of meconium ileus and at necropsy.

CF was confirmed at necropsy. Where faeces were collected, only 2 infants' specimens had a ratio $<4{\cdot}0$. In one, the infant was receiving pancreatic enzyme supplement and, in the other, the infant had been diagnosed early by a sweat test before symptoms became apparent. The sweat test was carried out, despite a negative meconium result, because the infant was known to be at risk. Five of the 9 infants were younger siblings of children with CF. Three of the 4 other infants (Cases 1, 4, and 6) had older normal siblings but all 3 mothers had had previous miscarriages.

Distribution of protease inhibititors in meconium, cord serum, and amniotic fluid. As the protease inhibitors in meconium are resistant to proteolysis, their distribution in meconium should be similar to their distribution in the major source of meconium serum protein whether it is amniotic fluid or vascular transudates. The distributions of protease inhibitors were estimated in 55 normal and 26 CF meconium specimens, in 55 cord sera and 50 amniotic fluids, and the α-1-TI: α-1-CI ratios were calculated (Table 4). The cord sera came from the same neonates as the normal meconium specimens. Although the concentration of the protease inhibitors in meconium from infants with CF was lower than in specimens from normal infants, the proportion of α-1-TI to α-1-CI in the two groups was not significantly different ($P>0{\cdot}2$). The α-1-TI : α-1-CI ratio in amniotic fluid was similar to that in normal or CF meconium (in both $P>0{\cdot}2$), but the α-1-TI : α-1-CI ratio (33·1) in cord sera was significantly higher than the ratio in meconium ($P<0{\cdot}001$).

The α-1-TI and α-1-CI content was estimated in 2 other meconium specimens not included in the analysis. The 1st was from an infant born to a mother with ZZ α-1-TI deficiency in whom the amniotic fluid would also be α-1-TI deficient. The ratio between the 2 protease inhibitors is 1·6:1. The infant's α-1-TI was typed as MZ and the α-1-TI: α-1-CI in the cord serum was 12·8:1. The 2nd specimen was from a child with oesophageal atresia without a tracheo-oesophageal fistula and in whom the specimen was unlikely to have amniotic fluid. The α-1-TI concentration was 6 mg/g dry weight but only trace amounts of α-1-CI could be detected in a 4% aqueous extract.

Discussion

BM mec-test strip compared with albumin immunoassay. There was little difference in specificity between the BM mec-test and the albumin assay. The test strip is quicker and simpler and can be carried out in the wards. However, if it is used by untrained personnel, it is likely that a higher incidence of false-positive results will be obtained than the 0·5% reported in this investigation. An overall false-positive rate of between 1 and 2·5% of all specimens screened has been reported (Stephan *et al.*, 1975; Schuttringer and Zinterhofer, 1978).

The albumin electroimmunoassay done in this laboratory gives a quantitative rather than a qualitative result; this result is obtained within half a day rather than the 24–48 hours needed for immunodiffusion. In specimens containing >20 mg albumin/g dry weight, an alb: α-1-TI ratio can be determined in the meconium and subsequent faecal specimens. Such a procedure reduces the false-positive results to a negligible number and, at the same time, confirms positive results. A quantitative albumin estimation may also be combined with limited sweat testing to reduce the number of false-negative results. This suggestion is based on the observation that in this study, 7 of the 9 false-negative specimens contained more than 1 mg albumin/g dry weight. Kollberg and Hellsing (1975) also reported that the 2 false-negative specimens in their study each contained >1 mg albumin/g dry weight. A sweat test for those infants in whom the meconium contained >1 mg albumin/g dry weight would mean testing about 34 infants in every 1000 live births, and such infants could be tested on their first clinic attendance. A sweat test should be done earlier if the meconium specimen is positive and the ratio remains positive in the stool; it should also be carried out if the child is a sibling of a known case. The high incidence of false-negative specimens from younger siblings of known CF children found in this study means that no reliance should be put on negative meconium test results from such children.

The cost of the 2 tests is difficult to determine because there are so many variables. The cost of material for the albumin immunoassay, provided the antiserum is prepared in the laboratory, is about one-10th that of the material for the BM mec-test; one penny per test compared with 10 pence per test. If commercial antiserum is used the cost of the albumin assay increases almost 3-fold. It is not possible to assess the cost of labour for the 2 tests as the salary of the investigator varies. In our laboratory, the time for testing 10 specimens by the BM mec-test was 5 min compared with 25 min for the albumin assay; the time of development of both tests was not included. Thus the labour costs are at least 5-fold higher with the albumin immunoassay and, consequently, the total cost for either test is similar.

Origins of false-positive and negative results obtained with meconium screening. Identification of the source of serum protein and particularly albumin in meconium is important if one is to explain the reasons for false-positive and false-negative results and consequently determine if it is possible to improve the specificity of the test. There is no definite evidence on the major source of albumin and other serum proteins in meconium but the consensus is that most of it comes from ingested amniotic fluid (Schutt and Isles, 1968; Prosser *et al.*, 1974; Ryley *et al.*, 1975), rather than from transudates into the gut from the fetal vascular system. The findings concerning the distribution of inhibitors in meconium, cord serum, and amniotic fluid support this view.

If amniotic fluid is the main source of meconium serum protein, the final concentration of albumin almost certainly reflects pancreatic enzyme activity but if there is a large contribution of protein from the fetus, it could be argued that raised meconium albumin concentrations in CF may reflect an increase in the intestinal transudation (Wiser and Beier, 1964; Rule *et al.*, 1970), especially from the lower part of the gut where proteolytic activity may be less. The results in this study show that serum protein originates from the same source in meconium specimens from healthy neonates and infants with CF, and are consistent with the suggestion that vascular transudates do not contribute substantially to the final protein content of meconium. Thus a raised albumin content in meconium from CF infants signifies deficient pancreatic enzyme activity in the fetal gut and similarly a false-negative meconium test means that the specimen was passed by an infant with CF who had normal pancreatic function at birth.

Those infants without CF who pass meconium with a raised albumin content could have reduced pancreatic function at birth. Gitlin *et al.* (1972) reported that before birth, a fetus daily ingests half the total volume of amniotic fluid and consequently as amniotic fluid volumes vary, so also does the amount of ingested protein from child to child. Reduced intestinal proteolytic activity coupled with a higher than average protein intake might lead to a final raised meconium albumin content. This would explain why the alb: α-1-TI ratio is effective in reducing false-positive results. The ratio compares the concentration of a protein liable to proteolysis, albumin, with the concentration of a protein resistant to proteolysis, α-1-TI. Thus the concentration of α-1-TI in meconium directly reflects the initial protein intake and will be high or low accordingly. The concentration of albumin, on the other hand, depends not only on its initial concentration but also on the extent of its proteolysis. A high initial albumin concentration together with reduced proteolytic activity may result in a specimen giving a positive albumin result. A specimen from another infant with the same reduced gut enzyme activity but in whom the initial albumin intake was low, may give a negative albumin result. The ratio in both specimens however will be similar.

Contamination by occult blood has been suggested as an alternative explanation for false-positive results, especially in preterm births (Griffiths *et al.*, 1976), because of the observation that many specimens containing albumin also gave a positive guaiac test. At the start of our study, we routinely tested 1% meconium extracts for occult blood with the Hema-Combistix (Ames Company, Bucks, England) which used the o-toluidine-peroxidase reaction for haem. The test was stopped after positive results were obtained with the first 100 specimens, only 2 of which contained any albumin. The specificity of the 2 tests is similar although the test stick is probably more sensitive than the guaiac test (Makarem, 1974). It is therefore not clear at the moment how important contamination by occult blood is in the generation of false-positive results.

CF screening

This study shows that current meconium tests for CF which appear to depend on the status of pancreatic function will miss about 25% of infants with the disease. If for any reason CF is suspected, little reliance should be put on a negative meconium test. Also any new test should be assessed according to what effect the presence or absence of proteolytic activity will have on the component being measured, as specificity will be increased only if it can be shown that there are changes in meconium composition caused by the underlying genetic lesion but independent of pancreatic activity. Such changes, if present, will probably be found in the mucin component of meconium.

The final assessment on whether screening for CF should become routine will depend not only on the specificity of tests but on the results of long-term treatment in cases where this was initiated soon after birth. If a better prognosis is related to early detection, even a test that detects 75% of affected children will contribute to the management of the disease when linked to a programme of treatment. In our opinion such studies are feasible with current meconium screening methods.

We thank Mrs J. Eady, Mrs G. Burns, and Mrs S. Rees for their technical assistance; the nursing staff of the various Cardiff maternity units for the conscientious collection of specimens; Dr S. Walker of the Department of Obstetrics and Gynaecology, UHW for the specimens of amniotic fluids. This work was supported by a research grant from the Medical Research Council and a grant from Boehringer Mannheim GmbH.

Curd and whey proteins in the nutrition of low birthweight babies

H. M. BERGER, P. H. SCOTT, CAROLINE KENWARD, P. SCOTT, AND B. A. WHARTON

Sorrento Maternity Hospital and Selly Oak Hospital, Birmingham

SUMMARY Some animals thrive more satisfactorily on a milk that contains whey and curd protein. For this reason human milk protein (which contains about 40% whey) may have some advantages over cows' milk protein (which contains about 15% whey) and so infants feeding formulae based on demineralised whey in which the protein has been modified to achieve a curd:whey ratio similar to that in human milk may also thrive more satisfactorily. As the exact situation in the human newborn is unclear, the effects of feeding a formula containing unmodified cows' milk protein (mainly curd) and one containing the same amount of modified cows' milk protein (curd and whey) were studied in 57 low birthweight babies during the first 3 months of life. During the early weeks of life the curd and whey group grew bigger, absorbed more nitrogen, and excreted proportionately less urea. These results suggest that a curd *and* whey formula has advantages in the protein nutrition of low birthweight babies, especially the preterm ones. We feel it would be unwise to reduce the protein content of a formula based on cows' milk below 15 g/l unless it was modified to achieve a larger proportion of whey protein and hence, among other qualities, more cysteine. Although some of the qualities of human milk protein can be mimicked by the use of demineralised whey formulae, others cannot.

Some animals thrive more satisfactorily on a milk that contains whey and curd protein, but the significance of this for the human baby is unclear. It is relevant to re-examine this point because of recent trends in infant feeding practice.

Whey protein (lactalbumin) is more effective in promoting the growth of rats, dogs, mice, and chicks than curd protein (casein) (Mueller and Cox, 1947); it is also more effective in regenerating the plasma albumin of protein-depleted dogs (Chow *et al.*, 1948), and in rats it has a higher 'biological value'—that is, retention of absorbed nitrogen is greater (Tomarelli and Bernhart, 1962). The significance of these observations for the human baby is not known. Empirically cows' milk protein (containing <15% of whey protein compared with >40% in human milk protein) has for many years been used with satisfaction for infant feeding; growth velocities of babies receiving a predominantly curd protein formula were similar to those receiving a curd and whey formula (Natelson *et al.*, 1955; Barness *et al.*, 1963), and nitrogen retention on cows' milk was similar to that of human milk (Waterlow *et al.*, 1960).

The Medical Research Council and Agricultural Research Council (1974) drew attention to two recent changes in the understanding of protein metabolism. Firstly, although the effective amino-acid patterns of human and cows' milk protein may be similar, the nutritive value of milk proteins does not depend only on the component amino-acids—e.g. the absorption of intact peptides by the intestine indicates that proteins of similar amino-acid pattern might, nevertheless, be handled quite differently. Secondly, a developmental deficiency in the newborn of the liver enzyme cystathionase may prevent adequate conversion of the high methionine content of curd protein into cysteine, so limiting nitrogen retention and making cysteine—an essential amino-acid for the newborn (Gaull *et al.*, 1972).

Empirically two trends in infant feeding make it relevant to reinvestigate the matter. Firstly, the reduction in protein concentration of infant feeding formulae to 1·5–1·8 g per 100 ml—i.e. well below that in cows' milk—makes consideration of protein

quality in these formulae more important than when most babies received formulae containing about 3·5 g cows' milk protein per 100 ml. The Department of Health and Social Security (1974) stated that the lower protein formulae should supply the 'essential amino-acids in amounts at least equal to those in an equal volume of breast milk'. More importantly, however, formulae based on demineralised whey are now available—such as Gold Cap SMA-S26, Osterfeed, and Cow and Gate Premium. One advantage of these formulae is their lower mineral content but, in addition, the curd:whey protein ratio has been altered to a value similar to that of human milk. This has a teleological appeal but it is unclear whether it has any other advantages.

For these reasons we studied the nutritional effects of curd and whey protein by comparing babies fed on two formulae: one based on demineralised whey with a curd:whey ratio similar to that in breast milk (group 1) and one containing unmodified cows' milk protein—i.e. mainly curd protein (group 2).

Patients and methods

Formulae. Fig. 1 gives details of the formulae used. The curd and whey formula was based on Gold Cap SMA-S26, and the curd formula was SMA. They were manufactured in special batches for this study by the manufacturer, John Wyeth, and the fat blend was identical. The main difference was the quality of the protein—predominantly curd protein in SMA given to group 2; curd *and* whey protein in the S26 given to group 1. However, as a result of the demineralisation process, the sodium and potassium concentrations in S26 were lower than those in SMA (Table 1). At reconstitution of the feeds, therefore, extra sodium (5 mmol/l as citrate) and extra potassium (4 mmol/l as citrate, 2 mmol/l as chloride) were added to the S26 to bring the concentrations of sodium, potassium, and chloride up to those in SMA. Citrate and chloride were chosen as the other anions because they are the main milk anions (Jenness and Sloan, 1970) and also because this combination lessened the differences in the electrolyte concentrations and acid base characteristics of the two formulae. There were still differences however; although the buffering capacity was similar, the pH was higher while the titratable acidity was lower than in the curd formula; we were unable to devise any method of eliminating this difference without introducing others. There was one other (unwanted) difference between the two formulae. The curd and whey formula contained less calcium and phosphate, thus partly reflecting its lower casein content (Jenness and Sloan, 1970).

Table 1 shows the composition of the reconstituted formulae and also the composition of human milk and unmodified cows' milk. In the curd and whey formula only 41% of the nitrogen was casein, so it contained more cysteine than the curd formula in which 82% of the nitrogen was casein.

Patients. Table 2 gives details of the patients. Beginning in January 1974 all low birthweight babies weighing 1·75–2·26 kg admitted to the special care baby unit of the Sorrento Maternity Hospital, entered the study if their mothers were unable to provide breast milk and had given their informed consent. Babies with severe respiratory distress requiring more than 40% ambient oxygen and not able to tolerate tube feeding were not studied.

Feeding regimen. The first feeds were given within 4 hours of birth to babies nursed initially at the optimum environmental temperature (Hey, 1971), subsequently aiming to maintain rectal temperature at 36·5–37·5°C. Indwelling polyvinyl intragastric

tubes were used if necessary. Appropriate weight-for-dates babies (weight 10-90th centile for gestation, Gairdner and Pearson, 1971) received 40 ml/kg during the first 24 hours of life, the volume increasing by 20 ml/kg each day, reaching 200 ml by the 9th day. Small-for-dates babies (weight < 10th centile) received 60 ml/kg on the 1st day, increasing by 30 ml/kg each day, reaching 200 ml by day 6. Thereafter, the volume remained at 200 ml/kg per day until day 21, after which the mothers were advised to give approximately 200 ml/kg per day according to appetite. For volume calculations, birthweight was used until this had been regained and then the volume was recalculated after each twice-weekly weighing. Plasma bilirubin concentrations exceeded 170 μmol/l (9·9 mg/100 ml) in 11 of group 2 and in 14 of group 1, so extra sterile water (30% of the above volume) was given to each baby until the bilirubin level had fallen to 170 μmol/l for 24 hours. As plasma bilirubin concentrations exceeded 250 μmol/l (14·6 mg/100 ml) in 3 babies in group 2 and 6 in group 1, these babies received phototherapy until these levels were below 220 μmol/l (12·9 mg/100 ml).

Method of assessment and analysis.

Anthropometry

This was performed at birth and at intervals thereafter by H.M.B. (Weight: Salter spring balance; length: Harpenden neonatometer; head and midarm circumference: steel tape measure; skinfold thickness: Harpenden skin calipers.

Plasma biochemistry

Samples of blood were collected by heel prick on days 2, 7, 11, and 21, four hours after the 6 a.m. feed. On days 60 and 90 parents were asked to give no milk for 8 hours before arrival but to give dextrose water as necessary.

The samples of blood were spun down within one hour and the plasma separated and stored at −20°C until analysis as follows: albumin (Northam and Widdowson, 1967), urea by application of the Berthelot reaction after enzymatic hydrolysis with urease, calcium (Baginski *et al*., 1973), and phosphate (Itaya and Ui, 1966).

Nitrogen balance and partition

24-hour samples of urine were collected from 17 baby boys on days 3, 10, and 19. Collection was made directly into a polyethylene container kept on ice and containing one thymol crystal. The urine was deep frozen until it was analysed for uric acid (Caraway, 1955), amino nitrogen (Goodwin, 1970), total nitrogen (Shahinian and Reinhold, 1971), urea and creatinine by standard autoanalyser methods.

Nitrogen balances were performed (Fomon, 1974) on 7 baby boys in each dietary group for 3- or 5-day periods ending on day 21 (group 1 compared with group 2 mean and SD: birthweight 2·06 ± 0·16 compared with 2·04 ± 0·16 kg; gestation 36 ± 2·1 compared with 36 ± 2·5 weeks). The total nitrogen in the formulae, urine, and faeces was determined by the method of Shahinian and Reinhold (1971).

Results

Clinical. Three of the babies in group 2 had convulsions in the first 2 days, and were withdrawn from the trial (Table 2). Neither was hypocalcaemic or hypoglycaemic but they both had low Apgar scores. Many babies did not complete 3 months, mainly because they were also receiving solid foods (usually wheat cereal). Both infant feeding formulae were well accepted with no undue vomiting, abdominal distension, or diarrhoea.

Anthropometry (Table 3). At birth the two groups of babies were similar in size apart from a slightly greater head circumference in group 1. By 21 days these babies had also become heavier and longer. This significant difference in weight gain was present in the preterm babies but not in the term light-for-dates babies (Fig. 2).

By day 90 the difference in growth was no longer significant in the small number of babies that remained in the trial. There were no differences at any age in mean skinfold thickness (using biceps, triceps, subscapular, umbilical, and quadriceps measurements) and mid upper arm muscle circumference (Gurney and Jelliffe, 1973), so the results are not given.

Plasma biochemistry (Table 4). Group 1 babies were less acidotic on days 7, 11, and 21 (these differences

had disappeared by days 60 and 90, so these results are not given). There was no correlation between base deficit on day 11 and weight gain during the first 3 weeks of life ($r = 0 \cdot 34$). There was no difference in plasma concentration of albumin, urea, calcium, and phosphorus throughout the 90-day study period, so the results are not given.

Nitrogen balance and partition (Table 5; Fig. 2). Group 1 babies absorbed a significantly greater proportion of the ingested nitrogen; mean nitrogen retention was higher but not significantly so. These babies excreted less urea nitrogen in the urine (day 10) and had higher urinary urea nitrogen:total nitrogen ratios (Fig. 3).

Discussion

During the early weeks the babies in group 1 grew bigger (particularly if preterm), absorbed more nitrogen, and lost less nitrogen as urinary urea.

Were these differences in growth and nitrogen metabolism due solely to the quality of the dietary protein? There were also differences in the acid base qualities of the formulae and indeed the babies in group 1 were significantly less acidotic.

Differences in the acid base status due to the protein quality were expected (Kildeberg and Winters, 1972) and, since addition of the citrate salts to the curd and whey formula equalised the potential base in the formulae, it is probable that the differences in the base deficits were caused by the dietary protein. A lower incidence of metabolic acidosis in babies fed a curd and whey formula was also found by Räihä *et al.* (1976) in studies on protein quality. Whatever the cause, however, it is unlikely that these acid base findings explain the differences in growth; there was no correlation between base excess and weight gain; the degree of acidosis was generally mild, and only 4 babies had base deficits great enough to be diagnosed as late metabolic acidosis (Svenningsen and Lindquist, 1973); Heird *et al.* (1976) suggested that acidosis affects growth by limiting appetite but in our study babies received a prescribed volume of feed.

It seems that the differences in growth velocity and nitrogen metabolism were at least primarily related to the difference in the quality of the dietary protein.

We are uncertain which of the various qualities of whey protein accounts for these differences. Whey protein leads to quicker gastric emptying and a lower intestinal buffering capacity than curd protein (Platt, 1961; Bullen and Willis, 1971) and this may be connected with the higher nitrogen absorption in group 1, but the differences in growth and nitrogen balance may be related to the higher cysteine content of whey protein (Table 1). The curd and whey formula supplied almost as much cysteine per unit volume and energy as breast milk and, unlike the curd formula, meets the estimated cysteine requirements of 23 mg per 100 kcal (45 μmol per 100 kJ) suggested by Fomon *et al.*, 1973. The differences in growth observed by us were not confirmed by others. Barness *et al.* (1963) found other biochemical differences but felt these had no clear advantage, although Räihä *et al.* (1976) concluded that the babies on a curd and whey formula paid a smaller 'metabolic price' to obtain their growth.

Clinical implications. Although the curd and whey formula had nutritional advantages, particularly in the preterm babies, these advantages were marginal. However, curd formulae containing 15 g/l of unmodified cows' milk protein provide less cysteine than does breast milk. If the protein and, therefore, cysteine content were further reduced to lower the renal solute load, then we suspect the reduction in growth velocity might be more pronounced than we observed. We consider it would be unwise to reduce the protein content of an infant feeding formula based on cows' milk below 15 g/l unless the protein was modified so that it included more whey protein. This caution is emphasised by susceptibility of cysteine to damage in the manufacturing processes (Pieniazek *et al.*, 1975).

Although the protein in the curd and whey formula was modified to resemble that of breast milk, nevertheless, it is still cows' milk protein. For example, the whey fraction contains lactoglobulin, more immunogenic than casein (Lebenthal, 1975), and very little lactoferrin; the curd fraction contains K casein which forms micellar complexes with certain minerals, accounting for their higher content in cows' milk (Jenness and Sloan, 1970). Cows' milk contains very little free taurine.

The babies were looked after by Miss A. Frogbrook and I. Sallis and their staff; Mrs J. King and Mrs S. Doughty helped to collect specimens and analysed the results; the Department of Medical Illustration, Birmingham Children's Hospital produced the figures, H. M. Berger held a Sheldon Clinical Research Fellowship of the West Midlands Regional Health Authority and later the Mary Crosse Research Fellowship; John Wyeth gave other financial support. We are grateful to all of them and to Mrs H. Bird and Mrs P. Cox for secretarial assistance.

Effect of tolazoline in severe hyaline membrane disease

N. McINTOSH AND R. O. WALTERS

Department of Paediatrics, University College Hospital, London

SUMMARY Tolazoline hydrochloride was given as a pulmonary vasodilator to 20 preterm infants with severe hyaline membrane disease requiring mechanical ventilation who developed persistent severe hypoxaemia. The drug was only given when deterioration persisted despite changes in ventilation techniques and thus there were no control infants. A significant improvement in arterial oxygenation was observed, particularly in those infants without intracranial haemorrhage or pneumothorax. Nine of 10 infants who had an obvious clinical response to tolazoline survived, whereas only 2 survived out of 10 who failed to respond, both being subsequently shown to have pneumothoraces. There appears to be a place for the use of tolazoline in a severely hypoxaemic infant with hyaline membrane disease who is being ventilated and in whom arterial oxygenation cannot be improved by further increase in the inspired oxygen concentration or by alteration of ventilator settings, provided pneumothorax has been excluded.

The normal increase in pulmonary vascular resistance in response to hypoxaemia occurs in an exaggerated form in the newborn infant. Pulmonary artery pressure rises to systemic levels with the reappearance of a transitional pattern of circulation (James and Rowe, 1957; Rudolph and Yuan, 1966). In infants with severe hyaline membrane disease, this response increases the right-to-left shunting of blood leading to increasing hypoxaemia, which is unresponsive to either increases in the fractional inspired oxygen concentration (F_{IO_2}) or to alterations in mechanical ventilator settings (Chu *et al.*, 1967; Stahlman *et al.*, 1972; Gersony *et al.*, 1976). Tolazoline hydrochloride has been suggested as a therapeutic agent for dilating the pulmonary arteries which might be used to improve arterial oxygenation (Cotton, 1965; Korones and Eyal, 1975; Goetzman *et al.*, 1976). This report describes our experience with the use of tolazoline in 20 consecutively admitted infants with severe hypoxaemia due to hyaline membrane disease.

Patients and methods

Twenty critically ill preterm newborn infants with severe hyaline membrane disease born between October 1976 and July 1977, developed persistent severe hypoxaemia while being mechanically ventilated, and were given 48 doses of tolazoline. The clinical details of the infants are shown in Table 1. None of the infants had polycythaemia or hypoglycaemia, and all were managed by methods previously described (Blake *et al.*, 1973). Six babies had coagulation abnormalities, 4 disseminated intravascular coagulation, and 2 had less specific abnormalities. Two infants had severe rhesus isoimmunisation requiring exchange transfusions.

The infants were all ventilated via an oroendotracheal tube with a constant flow pressure-controlled ventilator (Bourns BP 200). Mean peak airway pressure (PAP) was 29 cm (range 20–40) H_2O; mean end expiratory pressure (EEP) was 3·5 cm (range 0–5) H_2O; median inspiration/expiration ratio (I/E ratio) 1:1 (range 1:2–3:1); mean respiratory frequency (f) 30/min (range 25–40/min).

Seventeen infants had umbilical artery catheters sited in the lower abdominal aorta. Fifteen of the catheters had oxygen electrodes at their tips (Searle), allowing the continuous monitoring of arterial oxygen tension (Pa_{O_2}) (Conway *et al.*, 1976). In all infants, frequent blood–gas analyses were performed* on arterial samples obtained from either the arterial catheters or peripheral arteries.

The indication for giving the first dose of tolazoline was deteriorating hypoxaemia in the presence of an inspired oxygen concentration of 100% ($F_{IO_2} = 1{\cdot}0$) and the failure to respond to various manipulations of ventilator settings intended to raise Pa_{O_2} (Blake *et al.*, 1973; Herman and Reynolds, 1973). In 10 infants the Pa_{O_2} was less than 20 mmHg, in 6 it was between 20 and 30 mmHg, in 3 between 30 and 40

*HMD = hyaline membrane disease, IVH = intraventricular haemorrhage, PIE = pulmonary interstitial emphysema, RF = renal failure, PT = pneumothorax, Rh = severe rhesus isoimmunisation (see text), S = septicaemia, C = coagulopathy (see text), PH = pulmonary haemorrhage, SAH = subarachnoid haemorrhage.

mmHg, and in the remaining infant the Pa_{O_2} was 66 mmHg. Subsequent doses of tolazoline were given in 11 infants, who responded to the first dose, and in whom hypoxaemia recurred. Chest *x*-rays were taken before the use of tolazoline if time allowed, so as to exclude pneumothorax as a cause for the infant's deterioration. In 7 infants, pancuronium bromide in a dose sufficient to paralyse spontaneous respiration (0·03–0·05 mg/kg repeated as necessary) was given without improvement before the administration of tolazoline.

The dose of tolazoline hydrochloride was 1–2 mg/kg body weight given over 30 seconds, into a scalp vein (10 infants), into another vein (2 infants), or into the umbilical artery (8 infants).

Ventilator settings were recorded before and after each dose of tolazoline. In the 15 infants in whom the abdominal aortic Pa_{O_2} was recorded continuously, the records were analysed to determine the Pa_{O_2} one min before and the peak Pa_{O_2} within 10 min after the administration of tolazoline. In addition blood–gas analysis was performed before and after each dose of tolazoline.

Mean airway pressure (MAP) was calculated for each of the ventilator settings, using the formula

$$\frac{(\text{PAP} \times \text{inspired ratio}) + (\text{EEP} \times \text{expired ratio})}{\text{inspired} + \text{expired ratio}}$$

and changes in Pa_{O_2} were determined from the blood–gas and abdominal aortic oxygen electrode data. MAP has been shown to correlate well with alveolar arterial oxygen difference at slow respiratory rates (Herman and Reynolds, 1973), and so was used to measure changes in ventilation which might have contributed to changes in Pa_{O_2}. Changes in pH, Pa_{CO_2}, and base excess (BE) were also noted.

Blood pressure was measured by ultrasound using a Doppler (1 infant) or by a transducer (Hewlett Packard) attached to the umbilical arterial catheter (12 infants).

Tolazoline administration is followed by peripheral vasodilatation (Grover *et al.*, 1961), and this was apparent in our infants. In 13 of them infusion of either whole blood, normal saline, or 5% sodium bicarbonate was needed after the administration of tolazoline to maintain an adequate circulating blood volume and a normal blood pressure.

The data obtained relating to each dose of tolazoline were analysed, using Student's paired or unpaired *t* test, as appropriate.

Results

Data obtained from continuously recorded abdominal aortic Pa_{O_2} are summarised in Table 2. An example of such a record showing the response to tolazoline from which these data were obtained is shown in the Figure. Data obtained from analysis of samples of arterial blood are summarised in Table 3.*

The 15 infants in which abdominal aortic Pa_{O_2} was continuously recorded received 41 doses of tolazoline (Table 2). There was a highly significant rise of 26 mmHg in the abdominal aortic Pa_{O_2} after tolazoline injection ($P<0{\cdot}001$), while $F_{I_{O_2}}$ and MAP did not change significantly.

Group	*Doses*	*Before tolazoline*			*After tolazoline*		
		Mean MAP (cm H_2O)	*Mean F_{IO_2}*	*Mean Pao_2 (mmHg)*	*Mean Δ MAP (cm H_2O)*	*Mean Δ F_{IO_2}*	*Mean Δ Pao_2 (mmHg)*
Response to all doses of tolazoline							
All patients (n = 15)	41	17·0	1·0	28	−0·02 (NS)	0	+26 $(P<0\cdot001)$
Group A (n = 9)	24	16·2	1·0	34	0	0	+38 $(P<0\cdot001)$
Group B (n = 6)	17	18·2	1·0	21	−0·05 (NS)	0	+8 $(P<0\cdot05)$
Response to 1st dose tolazoline only							
All patients (n = 15)	15	18·6	1·0	22	+0·2 (NS)	0	+39 $(P<0\cdot005)$
Group A (n = 9)	9	17·4	1·0	27	0	0	+56 $(P<0\cdot005)$
Group B (n = 6)	6	20·3	1·0	14	+0·4 (NS)	0	+14 $(P<0\cdot01)$

Group A: Infants without intracranial haemorrhage or pneumothorax; Group B: infants with either intracranial haemorrhage (4) or pneumothorax (2).

In the 9 infants who were not shown subsequently to have intracranial haemorrhage or pneumothorax (group A), the mean rise of 39 mmHg in abdominal aortic Pao_2 was significantly greater than in the 6 infants with either intracranial haemorrhage or pneumothorax (group B) in whom the mean rise in abdominal aortic Pao_2 was 8 mmHg $(P<0\cdot01)$. The response to tolazoline was more marked after the first dose, the mean rise in abdominal aortic Pao_2 in all patients being 39 mmHg. In group A the mean rise of 56 mmHg was significantly greater than in group B, in which the mean rise was 14 mmHg $(P<0\cdot01)$.

Blood-gas data were obtained before and after 33 doses of tolazoline in 20 infants (Table 3). There was a significant rise of 21 mmHg in Pao_2 after tolazoline injection $(P<0\cdot01)$ which occurred despite a fall in F_{IO_2}, while MAP did not change significantly. No significant change in pH, Paco_2, or base excess occurred. In the 11 infants who were not shown subsequently to have intracranial haemorrhage or pneumothorax (group A), the mean rise in Pao_2 was 26 mmHg compared with the mean rise in Pao_2 of 10 mmHg in the 9 infants with intracranial haemorrhage or pneumothorax (group B). This difference is not statistically significant. If the 2 patients with pneumothorax are excluded from group B, the mean rise in Pao_2 for the group is 4 mmHg which is significantly different from the rise in group A $(P<0\cdot05)$. When only the response to the first dose of tolazoline is considered, the mean rise in Pao_2 after tolazoline was 33 mmHg $(P<0\cdot01)$ which occurred despite of a fall in F_{IO_2}, while MAP did not change significantly. In group A the mean rise in Pao_2 of 49 mmHg was significantly greater than in group B in which the mean rise was 14 mmHg $(P<0\cdot05)$.

Discussion

Tolazoline hydrochloride is chemically related to the sympathomimetic amines and histamine. It is a short-acting alpha adrenergic blocking agent, but in the doses used in the clinical situation this effect is negligible. It is also a histaminic agent and has a direct nonadrenergic relaxant action upon vascular smooth muscle, the vasodilator effect being greatest in regions where vasoconstriction is most pronounced (Grover *et al.*, 1961). Tolazoline has been shown to relieve pulmonary vasoconstriction and in this respect it is believed to be most effective in those cases where pulmonary vascular resistance is increased due to a generalised constriction of hypertrophied small muscular arteries (Grover *et al.*, 1961). This situation is similar to that seen in severe hyaline membrane disease with hypoxaemia, and pulmonary vasospasm has been demonstrated in such infants by Chu *et al.* (1967). The possible value of tolazoline in the management of severe hypoxaemia in infants with hyaline membrane disease has been suggested (Goetzman *et al.*, 1976).

In our 20 deteriorating infants we demonstrated a significant rise in arterial Pao_2 in response to tolazoline. The babies acted as their own controls as the drug was given only as a last resort when all other treatments had failed and it was felt that death was imminent. In infants who did not have intracranial haemorrhage or pneumothorax as a cause for their severe refractory hypoxaemia the improvement was more pronounced. The difference in response to tolazoline between the two groups was more marked with the first dose than with subsequent ones.

Of the 10 infants who had an obvious clinical

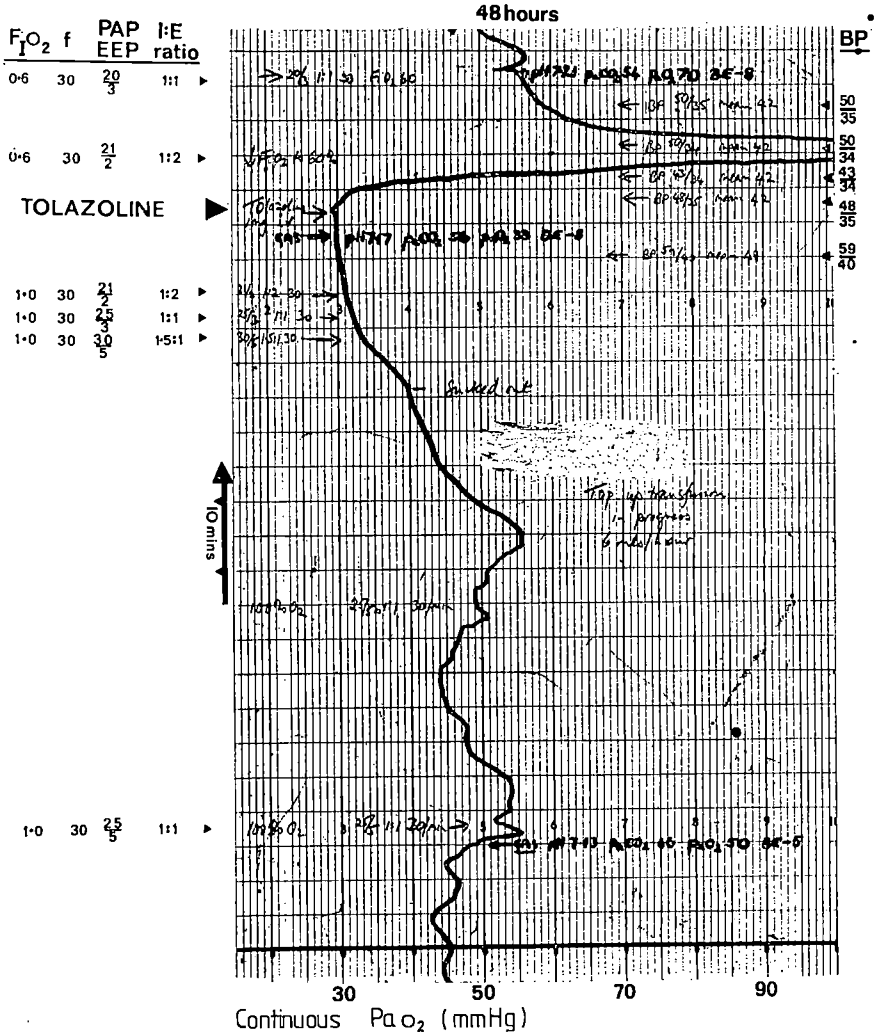

Figure *Continuous Pao_2 trace from baby in group A given intravenous tolazoline. Read trace from below up. Abbreviations as in text.*

response to tolazoline, 9 survived, whereas only 2 out of 10 who failed to respond survived; both of these infants were subsequently shown to have pneumothoraces which were satisfactorily drained. These results suggest that the improvement in oxygenation resulting from the administration of tolazoline may lead to better survival in a group of infants who would otherwise have a high mortality. It is suggested that the mechanism for improvement is the breaking of the progressive vicious circle of increasing hypoxaemia, acidosis, and pulmonary vasoconstriction.

The known potential side effects of tolazoline are related to systemic hypotension and histaminic effects on the gastrointestinal tract. In our series systemic hypotension was not a significant problem because care was taken to maintain the circulating blood pressure. However, we consider that monitoring blood pressure is essential if this drug is used. Renal failure was observed in one patient, who died. This could be attributed in part to tolazoline, but the failure may have been due to hypoxic damage caused before the use of tolazoline. Extreme irritability accompanied by bloodstained cerebrospinal fluid observed in 2 patients, both of whom survived, might have resulted from leakage of red

cells through a distended cerebral capillary bed to the cerebrospinal fluid. In neither case presenting in this manner was there apparent abnormality in the coagulation status which has been associated with subarachnoid haemorrhage (Chessells and Wigglesworth, 1971). Gastrointestinal problems were not encountered, although a potential hazard from reduced splanchnic flow might be necrotising enterocolitis; abdominal distension and haemorrhage have been well described by Goetzman *et al.* (1976).

We agree with Levin *et al.* (1976) that one definite indication for tolazoline is hypoxaemia with demonstrable difference between upper and lower body Pao_2, implying persistence of transitional right-to-left circulation through the ductus arteriosus. This, in fact, occurred in only one baby in our series.

We conclude that there is a place for the use of tolazoline in a severely hypoxaemic infant with hyaline membrane disease who is being ventilated with an inspired oxygen concentration of 100% and in whom the Pao_2 is unresponsive to alteration of ventilator settings. In these cases where chest movement is clinically normal and where pneumothorax has been radiologically excluded, tolazoline may have a dramatic effect.

We thank Professor E. O. R. Reynolds for encouragement throughout the study, and to medical and nursing staff on the Neonatal Unit at University College Hospital for co-operation.

Factors affecting neonatal jaundice

BEN WOOD, PHYLLIS CULLEY, CLAUDIA ROGINSKI, JEAN POWELL, AND JOHN WATERHOUSE

Birmingham Maternity Hospital, University of Birmingham

SUMMARY Plasma bilirubin was estimated on 690 term infants on about the 6th day of life. Perinatal factors were recorded and the results analysed. Hyperbilirubinaemia was defined as a level >205 μmol/l (12 mg/100 ml) and this was present in 20% of cases. Three factors—epidural analgesia, breast feeding, and poor weight recovery—showed highly significant associations with jaundice. The relative importance of these is discussed and compared with recent reports. Induction of labour, for reasons other than postmaturity, and a gestational age <39 weeks showed a slightly increased incidence of jaundice. There was no correlation with other factors tested including oxytocic drug administration. Despite the high incidence (20%) of hyperbilirubinaemia, only 2.5% infants needed treatment and none required exchange transfusion. Radical changes in obstetric management or infant feeding are not indicated.

Since the claim by Mast *et al.* (1971) and Quakernack and Mast (1971) that oxytocic drugs were related to an increased incidence of neonatal jaundice, reports on this and on other maternal or perinatal factors have shown conflicting results (Ghosh and Hudson, 1972; Davidson *et al.*, 1973; Eden *et al.*, 1974; Gould *et al.*, 1974; Chalmers *et al.*, 1975). It was therefore decided to carry out a prospective study at the Birmingham Maternity Hospital taking into account the recent changes in obstetric and paediatric practice to assess incidence, related factors, and clinical implications.

Method

Two representative lying-in wards at the hospital were chosen. 903 mothers were delivered of liveborn infants between September 1974 and July 1975 inclusive, but 180 of these babies were discharged before 6 days and a further 33 were preterm, of low birthweight, Coombs-positive, or delivered by ventouse, and so were excluded. The 180 infants were compared with the remaining 690 and no significant differences were found regarding ethnic group, social class, gestation, or birthweight. There were however rather fewer vertex deliveries and rather more forceps and caesarean births among the infants who stayed the full 6 days. Otherwise the 690 infants studied were representative of term babies delivered at that time in the hospital.

The maternal history, birth details, and infants' data were recorded on a proforma suitable for computer analysis.

Assessment of jaundice. As the plasma bilirubin (PB) level rises and then falls in the normal newborn during the first week, the timing of the samples needs to be as constant as possible to give comparable results. Sampling was therefore arranged to coincide with the metabolic screening test on about the 6th day. Those infants showing clinical jaundice had PB levels measured earlier and 17 infants with PB levels >308 μmol/l (18 mg/100 ml) before the 6th day received phototherapy. In these the highest recorded levels were used in the analysis. PB was measured by a modification of the method of White *et al.* (1958).

Despite a general alertness for jaundice, surprisingly high PB levels were obtained for the first time at the routine 6th day heel prick in some babies. 32 (4·4%) had PB levels >205 μmol/l (12 mg/100 ml) and 9 (1·2%) >256 μmol/l (15 mg/100 ml). These might have been missed, emphasising the need for all infants to have blood samples taken if the true incidence of hyperbilirubinaemia is to be obtained.

Results

A distribution curve for the whole series was plotted

within 34 μmol/l (2 mg/100 ml) groups (Figure). The interplay of the various factors and the levels of PB were repeatedly analysed on the computer. It was found that a level of 205 μmol/l (12 mg/100 ml) and above showed the most significance, and this was defined as hyperbilirubinaemia. Mean PB levels were also recorded for comparison.

The following factors showed no effect on jaundice: ethnic group, ABO blood group, maternal age, time of year, type of delivery, birthweight, birth rank, vitamin K administration, sex, maternal toxaemia, and social class.

The gestational age of all these infants was >37 weeks and there was a slight increase both of mean PB levels and of hyperbilirubinaemia in those <39 weeks (Table 1). The mean gestational age was taken into account in each subsequent analysis and it showed a similar distribution throughout the different clinical groups.

Six clinical groups remained to be analysed further: previous contraceptive pill taking by the mother, oxytocic drug, labour onset, epidural analgesia, method of feeding, and weight recovery.

Table 2 shows how these clinical groups compared in respect of mean PB levels and percentage of babies with hyperbilirubinaemia. There was no difference in respect of pill taking or oxytocic administration. When induction of labour was analysed for the whole group there was no apparent effect but when the cases were divided into those induced for prolonged pregnancy and those induced for other reasons there were significant differences.

Epidural analgesia, weight recovery, and breast or artificial feeding all gave highly significant differences in respect of percentage jaundice and, the last two, in respect of mean PB levels as well. The clinical groups were therefore analysed a further three ways according to whether the mothers had received epidural analgesia or not, whether the baby regained birthweight above or below 95%, and whether it was wholly breast or artificially fed. Epidural analgesia and weight recovery did not alter the results in Table 2, but taking the 590 wholly breast-fed or wholly bottle-fed babies there were some minor changes. The mean PB level of the breast fed 'pill' group was significantly higher than the 'no pill' but the difference in hyperbilirubinaemia was not. Oxytocic drug and labour onset remained virtually the same. The interrelationships between the three

significant factors is further examined in Table 3. The effect of epidural analgesia on hyperbilirubinaemia was reduced in significance and this was more apparent in the breast-fed than the artificially-fed group, probably because the size of the sample was smaller. Poor weight recovery did not show an effect in the artificially-fed infants so it was concluded that breast feeding itself rather than any concomitant underfeeding was the more important factor.

Discussion

An increasing incidence of neonatal jaundice has been reported by several authors (Campbell *et al.*, 1975; Sims and Neligan, 1975; Smith and Wilson, 1978), while in Birmingham the incidence of hyperbilirubinaemia (>205 μmol/l) has apparently risen from 5·6% (Wood *et al.*, 1962) to 20% in 1975. These figures are not strictly comparable however because in the early years routine blood tests were not done and, as already shown, 4% of babies with significant levels might have been omitted. Despite this, and a recent questionnaire to the contrary (Friedman *et al.*, 1977), it appears that in many centres there has been a real increase, although this may have levelled off since 1972 (Friedman *et al.*, 1978).

The incidence of hyperbilirubinaemia reported from different centres ranged from about 5% in Belfast (McConnell *et al.*, 1973), 8% in Liverpool (Beazley and Alderman, 1975), 9% in Cardiff (Davies *et al.*, 1973), 10% in Edinburgh (Chew and Swann, 1977), 12% in London (Campbell *et al.*, 1975), and 21% in Oxford (Calder *et al.*, 1974), which alone closely approached our own figure of 20%.

The pill and breast feeding. Since the report of Wong and Wood (1971) of a higher incidence of jaundice in breast-fed babies of mothers who had previously taken the pill, the oestrogen content has been much reduced and this may be the explanation (Wong, 1974) for a difference (P < 0·05) being seen only in mean PB levels and not in hyperbilirubinaemia in the present series.

Oxytocic drugs. The dose of oxytocin in this series was low (< 10 units for most labours) which supports the view of Davies *et al.* (1973) and Beazley and Alderman (1975) that the effect, if any, is likely to be dose related. Our results showed no increase in either mean PB levels or of hyperbilirubinaemia whether the oxytocin was given to induce or augment labour.

Labour onset. Only when induction was divided according to its two main indications—prolonged pregnancy, on the one hand, or for obstetric or medical reasons, on the other, was there any difference. Any pronounced increase of preterm induction as a result of individual hospital policy would be liable to increase the jaundice risk, as shown in Table 1. This accords with the findings of Calder *et al.* (1974) and Sims and Neligan (1975) where the concept of enzyme priming in spontaneous labour was raised.

Epidural analgesia. Davies *et al.* (1973), Campbell *et al.* (1975), Sims and Neligan (1975), and Friedman *et al.* (1978) question the use of bupivacaine as a cause of hyperbilirubinaemia, and this study showed a highly significant difference. Whether this was due to the analgesic drug itself or to a related factor is uncertain. It is unlikely to be due to any post-delivery drug administered to the mother and secreted in her milk as it was also shown in the artificially-fed babies. Sims and Neligan (1975) thought that the association of epidural with jaundice in their series was probably because of the need for efficient pain relief during high dose oxytocin infusion after deliberate induction of labour. If this was the explanation in our epidural cases, one would expect that the proportion of deliberately induced babies would be significantly higher in those with hyperbilirubinaemia than in the rest. In fact the percentages were 43 and 38% respectively, showing no significant difference. The forceps rate in epidurals was as expected higher (52·5%) compared with nonepidurals (9%). However the incidence of hyperbilirubinaemia in the epidurals was the same whether they were delivered by vertex (22·6% hyperbilirubinaemia) or by forceps (21·6% hyperbilirubinaemia), again suggesting that the epidural is the relevant factor.

Feeding and weight recovery. From Table 3 it appears that breast feeding is more relevant than poor weight

LIBRARY

gain. In Newcastle, Sims and Neligan (1975) also noted such a relationship and felt that it could not be explained by the jaundice causing the weight loss as the lowest weight was usually recorded on the 3rd day while the peak bilirubin level was not reached before the 4th or 5th day. This suggests that some human milk may contain an icterogenic factor but this may not necessarily be an endogenous one.

Other factors. In a comprehensive analysis of some 20 different drugs administered to the mother in labour, Drew and Kitchen (1976) showed that aspirin, barbiturate, and some others lowered the newborn baby's PB level on the 2nd and 3rd days while diazepam and oxytocic drugs raised it. The effect was small and probably only of significance in the at risk infant. It would be interesting to extend that kind of investigation in both breast-fed and artificially-fed infants during the first week of life.

In conclusion it appears that the high incidence of jaundice in this series was probably associated with the frequency of epidural analgesia (74%) and of wholly breast-fed babies (45%). As stated the only other report of a similar incidence of hyperbilirubinaemia was from Oxford (Calder *et al.*, 1974) where 85% of mothers had epidurals and 29% wholly breast fed their infants.

These factors overshadowed the others so that previous pill taking by the mother and oxytocic administration in the relatively low dosage used had no effect. Induction of labour showed its expected effect only if cases induced for postmaturity were excluded.

The question remains as to whether the bupivaine and the breast milk themselves are icterogenic or whether the women concerned received different analgesic or hypnotic drugs from the others and these might be the active agents.

While obvious jaundice in her infant can cause maternal anxiety and may delay discharge from hospital it should be noted that only 17 (2·5%) of the 690 infants had PB levels >308 μmol/l (18 mg/100 ml) at which phototherapy or feed change was instituted. None reached 427 μmol/l (25 mg/100 ml) which was the agreed level for exchange transfusion. Evidence for long-term handicap after nonhaemolytic jaundice of this degree is tenuous. The findings by Boggs *et al.* (1967) and later by Scheidt *et al.* (1977) of delayed psychomotor development at 8 months and one year in infants with neonatal PB levels of about 256 μmol/l made inadequate allowance for gestational age at birth and later reports on these children are still awaited. 17 of 18 children found to be deaf by Fenwick (1975) after similar PB levels had haemolytic disease and, in the 18th, the child's mother had an obscure jaundice. In an earlier series of 371 jaundiced infants reported by us (Culley *et al.*, 1970), full neurological and psychomotor examination at age 5 years showed no ill effects unless PB exceeded 342 μmol/l (20 mg/100 ml).

There is therefore no reason for doctors to reduce their advocacy of breast feeding or to make radical changes in the management of labour until the responsible factors have been more clearly identified.

Childhood asthma. A controlled trial of family psychotherapy

BRYAN LASK AND DUNCAN MATTHEW

The Hospital for Sick Children, London

SUMMARY In an attempt to evaluate the effectiveness of family psychotherapy as an adjunct to conventional treatment in childhood asthma, children with moderate to severe asthma were randomly allocated to a control group or to an experimental group; the latter group received 6 hours of family treatment during a 4-month period, and both groups had standard medical treatment. While there was no significant difference between the two groups on three parameters, the experimental group were significantly better in day-wheeze score and thoracic gas volume. These results suggest that family treatment in selected cases may have a place in the overall management of childhood asthma, and that more research with larger numbers of children is necessary.

While it is accepted that the basic abnormality in childhood asthma is the combination of bronchial lability and atopic status (König and Godfrey, 1973), it is well known that emotional factors play an important part in its aggravation and maintenance (Purcell *et al.*, 1969; Graham and Rutter, 1970; Godfrey and Silverman, 1973; Pilling, 1975; Williams, 1975). McNichol and his colleagues stated that 'patients with severe ventilatory disturbance should be assessed psychologically and the family interrelationships assessed' (McNicol *et al.*, 1973). The implication of this is that psychological methods of treatment as an adjunct to medication may be indicated either for the asthmatic child or his family.

Despite the many reports on emotional aspects of childhood asthma, there have been very few controlled studies of psychological methods of treatment. Some modest claims have been made for the effectiveness of such behavioural methods of treatment as conditioning and relaxation (Lukeman, 1975; Kotses *et al.*, 1978), while Pinkerton (1967) showed that a group of 13 asthmatic children treated with short-term individual psychotherapy had a lower relapse rate than did a matched control group of 12 children. More recently spectacular success was claimed for the use of family psychotherapy in the treatment of intractable childhood asthma (Liebman *et al.*, 1974). The validity of this claim is diminished by the absence of a control group.

However on the basis that 'it is at home with persons who are most loved (or at times hated) that emotional relationships are most intense, and most likely to produce symptoms' (Apley and Mac Keith, 1968), we decided to test the effectiveness of family psychotherapy as an adjunct to standard medical management of childhood asthma. No controlled studies have been published on family psychotherapy for any childhood conditions.

Methods

The children were attending the asthma clinic at a postgraduate teaching hospital, where many patients are referred for a 2nd, or even a 3rd, opinion. Any child between the ages of 4 and 14 with grade C or D asthma (as defined by McNicol and Williams, 1973) was considered eligible for the study.* Their families were then randomly allocated to the experimental (group A) or control group (group B). Three of the families had more than one asthmatic child, and so all were included in the assessments. Initially, group A comprised 17 families with 21 asthmatic children, and group B comprised 16 families with 16 asthmatic children. The two groups were homogeneous with respect to severity of asthma, age (range 4–14), social class, and psychological health. There were more boys than girls in group A, but as the natural history of asthma does not vary between the sexes

**Grade C* children with a continuing history of episodic asthma over a number of years.
Grade D children with a current history of very frequent or chronic unremitting asthma.

(McNicol *et al.*, 1973), this was not considered to matter.

In group A 10 children were using cromoglycate (Intal) or beclomethasone (Becotide) regularly, and 8 were using only bronchodilators. In group B 6 children were using cromoglycate or beclomethasone regularly, and 5 were using only bronchodilators. Two children in group A and one in group B had received intermittent courses of corticosteroids before the trial but not during it.

Each child was assessed using diary cards, recording day-wheeze and activity limitation on a 0–3 scale of ascending severity, and the peak expiratory flow rate (PEFR) was measured before giving the morning or evening medication. These measurements were made during a 6-week baseline period before the start of treatment, and were repeated during a similar 6-week follow-up period one year later. One measurement of forced expiratory volume ($FEV_{0\cdot75}$) and thoracic gas volume (TGV) was made during each period. In addition, the children and families were fully assessed psychologically before treatment began, and the families classified according to Schneidermann—as emotionally healthy, moderately disturbed, or poorly adjusted (Schneidermann *et al.*, 1976).

Children in group B were seen and appropriately treated by the paediatrician at 3-weekly intervals during a 4-month period. Drug regimens were monitored and changed if necessary, and general management of the asthma was discussed, but there was no specific attempt to clarify or alter family relationships. Children in group A were seen by the paediatrician in the same way but these children also attended with their families on the same day for 6 one-hour sessions of family psychotherapy. Details of this treatment are to be found elsewhere (Lask, 1979; Lask and Kirk, 1979) but a brief summary is given below.

Family psychotherapy. This has as its conceptual focus the whole family system with particular emphasis on understanding the individual's symptoms and behaviour as arising from and feeding back into the general family system of interaction. The family therapist would meet the *whole* family together and, in the case of an asthmatic child, would focus on such themes as the varying attitudes to the illness, the doctor and the medication, the fear of death, and the experiencing of painful and frightening emotions. By dealing with such themes and helping to adjust attitudes away from the extreme and towards the more realistic, he would work towards an improvement in the psychological wellbeing of the family. In this way there would be an alleviation of some of the stresses which, in interaction with other physical factors, contribute to the recurrence of asthmatic attacks (Pinkerton, 1967).

Results

Some children who were initially assessed were not included in the follow-up. One family in group B dropped out after the initial assessment, and one family in each group dropped out after the first session. A further 3 children in group B were excluded from follow-up as one of them had failed to attend most of the appointments while two others were sent to special boarding-schools for asthmatic children because their health had so deteriorated. Finally, 3 children in group B, were unable to cooperate in the measurement of TGV. Consequently, at final follow-up there were 18 children in group A and 11 in group B of whom 3 had each missed one test.

The peak flow was expressed as percentage predicted normal for height, and the mean morning and evening peak flows for the two 6-week assessment periods were determined (Table 1). There was no significant difference between the two groups, but there was a significant improvement between baseline and follow-up scores in group A, but not in group B ($P<0\cdot005$, paired *t* test).

The $FEV_{0\cdot75}$ and the TGV were expressed as percentage predicted normal for height (Table 1). There was no significant change in $FEV_{0\cdot75}$. TGV is an index of lung overinflation and therefore if this falls there has been an improvement. There was a significant improvement in TGV in group A compared with group B ($P<0\cdot02$, rank sum test).

The activity and day-wheeze scores were expressed as the total score for each 6-week baseline and follow-up period (Table 2). There was no significant difference in change of activity score, but the day-wheeze score improved in favour of the experimental group ($P<0\cdot01$, rank sum test).

The results of the respiratory function tests and the symptom scores expressed as the differences

Discussion and conclusions

Although the number of children in this study was small, we believe that the findings warrant a more detailed evaluation of such treatment. That there should be a significant improvement in an objective test of respiratory function is in accordance with the conclusions of Pinkerton (1967) that many studies seem to indicate that psychodynamic factors are contributing to most cases of childhood asthma, and in turn will affect ventilatory function. We believe that the family treatment has helped to alleviate psychopathology within the family, and thus has contributed to an alleviation of the asthma. As we know of no other controlled studies showing improved respiratory function in asthmatic subjects after psychotherapy, and family therapy itself has been the subject of very few controlled studies, this approach should be more fully evaluated. Further studies should be on a much larger number of children, and, if possible, allowance should be made for the effect of increased attention. It should be added that the time allotted to the family psychotherapy was relatively short. Liebman *et al.* (1974) treated such families once a week for 1½ hours at a time for a one-year period. We recommend a compromise between the two. We suggest that family therapy may have a part to play in selected cases of childhood asthma, and especially in those cases where the asthma is not being well controlled with conventional treatment methods.

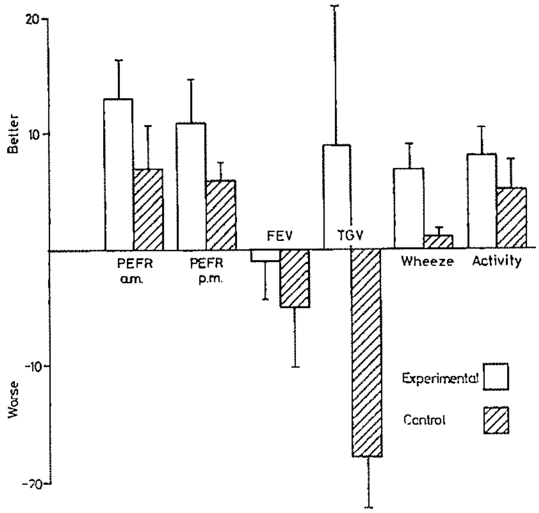

Figure *Differences (and SEM) between the baseline and follow-up values as shown in Tables 1 and 2.*

We are indebted to Mrs Marilyn Kirk, Mrs Ruth Levere, and the staff of the Respiratory Function Laboratory for help, to the Sembal Trust for financial assistance, to Professor P. Graham, Dr A. Bentovim, and Dr E. Hey for advice, and to Miss Rita Nani for typing the manuscript.

Antigen-antibody complexes in the serum of patients with juvenile chronic arthritis

H. MORAN, B. M. ANSELL, J. F. MOWBRAY, R. J. LEVINSKY, AND J. F. SOOTHILL

The Hospital for Sick Children, Institute of Child Health, and St Mary's Hospital Medical School, London

SUMMARY IgG-containing antigen-antibody complexes were detected in the sera of all of 7 patients with the systemic form of juvenile chronic arthritis, usually at high levels. Only 9 of 25 patients with the polyarticular form had such complexes, usually at low levels. Three patients had low levels of serum IgA which were probably drug induced; the one patient with low C2 and the 3 with low yeast opsonisation were probably not more than to be expected in a random population.

The aetiology and pathogenesis of juvenile chronic arthritis (JCA) remains unknown, but it has a number of features in common with chronic antigen-antibody complex disease—especially the joint, eye, and skin manifestations. Deposition of immunoglobulin and complement in the joints (Munthe and Natvig, 1972) is consistent with this, but we know of only one report of tests for presumed antigen-antibody complexes (aac) in the blood of patients with JCA (Rossen *et al.*, 1977) and they were confined to those with the systemic form of the disease. We therefore report our results of IgG containing aac in patients with systemic and polyarticular JCA.

It has been suggested that persistent circulation of aac results from defects of the clearance functions —antibody, complement, and phagocytes (Soothill and Steward, 1971), and immunodeficiency, especially of IgA, is associated with a range of immunopathological diseases (Amman and Hong, 1971; Soothill, 1976). IgA deficiency is found in a significant minority of JCA patients, apparently as a primary defect (Cassidy *et al.*, 1977; Barkley *et al.*, 1978). Low levels of the second component of complement (C2), interpreted as indicating heterozygosity for the deficiency, have also been reported in association with JCA (Glass *et al.*, 1976). Other complement components are usually normal although some variation occurs during active disease (Bianco *et al.*, 1971). A common defect, apparently of the alternative pathway of complement, detected by defective opsonisation for yeast phagocytosis, is associated with a similar range of diseases as is IgA deficiency (Miller *et al.*, 1968; Soothill and Harvey, 1976, 1977). We have therefore measured, in addition to circulating aac, total haemolytic complement, C2, C3, and C4, IgA, IgG, and IgM, and the opsonisation of yeast for phagocytosis by normal polymorphonuclear leucocytes, in the JCA patients.

Materials

42 patients suffering from JCA (for diagnostic and classification criteria see Ansell and Wood, 1976), age range 6 to 15 years, were studied. 30 had polyarticular disease—23 seronegative and 7 seropositive; 7 had acute systemic disease (they were younger than the rest—age range 4 to 11 years), and 5 had amyloidosis complicating seronegative systemic disease. All were established patients receiving various forms of treatment. Sera from 19 children (age range 2 to 13 years) in hospital for non-immunological disease (largely cold surgery) were also studied.

Methods

Antigen-antibody complexes were measured by the method of Levinsky and Soothill (1977). EDTA was added to serum separated within 3 hours of blood collection, and the released C1q was removed by reaction with insolublised IgG. The serum was then added to a low affinity rabbit IgM antihuman IgG reagent, and the residual capacity of the latter to

agglutinate IgG coated latex, was measured by counting unagglutinated particles on a Coulter counter. Total complement was measured using an autoanalyser haemolytic method (modified from Nydegger *et al.*, 1972). It was also adapted for measuring C2, using mixtures of a C2-deficient serum (ED), and the test sample. Results were expressed as % of standard. IgG, IgA, IgM, and C3 were measured by a modification of the radial diffusion method of Fahey and McKelvey (1965). Yeast opsonisation was measured by the method of Soothill and Harvey (1976). Results were expressed as opsonisation index (yeasts per polymorph).

Results

The Figure shows the levels of aac in the sera of patients and controls. The maximum inhibition of agglutination by the latter was 20%, which is consistent with the published upper limit of normal (Levinsky and Soothill, 1977). 10 of the 23 patients with seronegative polyarticular disease had raised levels; in only 3 was the value greater than 30%. All 7 patients with systemic disease had raised levels of aac which were considerably higher than those with polyarticular disease. None of the patients with seropositive disease or amyloidosis had raised levels.

Immunoglobulin and complement were measured in 30 patients with polyarticular disease, positive or negative for rheumatoid factor. IgG, IgM, C3, and haemolytic complement values were either normal or high compared with the age-related normal ranges used in the department. This is consistent with previous reports in JCA. IgA was low in 3 patients, all of whom were receiving drugs which could have explained it, and yeast opsonisation was low (<2·5 Y/P) in 3 (2·30, 2·10, and 1·60); all these 6 had polyarticular seronegative disease.

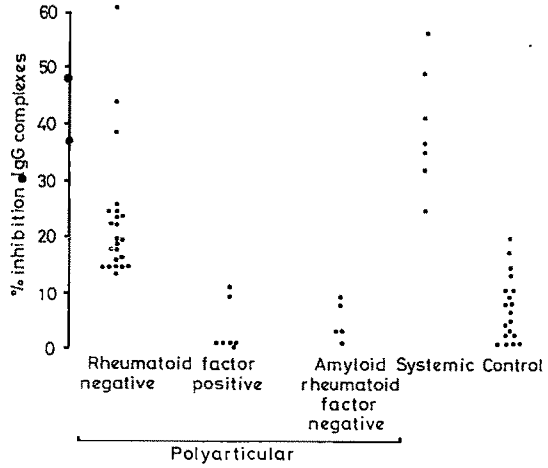

Figure. *Levels of IgG-containing antigen-antibody complexes in children with polyarticular and systemic juvenile chronic polyarthritis expressed as percentage inhibition of agglutination of IgG coated latex by rabbit IgM antihuman IgG reagent.*

Discussion

The high levels of IgG-containing aac in the serum of patients with the systemic form of JCA is consistent with the previous report (Rossen *et al.*, 1977), and with the hypothesis that they may play a part in the pathogenesis of this disease. In contrast, fewer than half of the patients with the seronegative polyarticular form of JCA had raised levels of aac and they had relatively low levels. This casts doubt on their pathogenetic role for this disease but, as the patients were studied at different stages of the disease, and on different treatments, these data do not refute that hypothesis. Antiglobulin antibodies (rheumatoid factor, and others) are low affinity antibodies to human IgG. Since these will agglutinate latex particles, they could produce false-negative results in our test and this could explain the apparent normal levels of aac in the children with positive rheumatoid factor JCA, but the decomplementing step, which entails removal of C1q with an insolublised IgG immunoabsorbate, would also remove rheumatoid factor, and so would lessen this effect. It is also possible, though, that this step might remove rheumatoid factor containing complexes. The negative finding in JCA with amyloidosis is an interesting new observation. Our data suggest that if the aac detected by this technique play a part in the pathogenesis of this disease, it is largely in the systemic manifestations.

Relatively low levels of serum IgA were detected in only 3 patients, and each had received drugs, such as penicillamine, which may have caused secondary IgA deficiency, so none of these patients is certainly among the minority of JCA with primary IgA deficiency (Cassidy *et al.*, 1973, 1977; Barkley *et al.*, 1978). The defect of yeast opsonisation is associated with a number of diseases which are also associated with IgA deficiency, so we measured it in these patients. The frequency (10%) of values below our diagnostic threshold (2·5) is not significantly greater than that of a healthy population (5%—Soothill and Harvey, 1976). Only one had a level of C2 which suggested heterozygosity for C2 deficiency; this is consistent with the reported incidence of such levels in the population and lower than in a previous report in JCA (Glass *et al.*, 1976). Our findings do not suggest that these deficiencies contribute importantly to the aetiology of JCA in our patients, and we could not investigate the relationship of the different possible immunodeficiencies to the aac findings. We can only assume that our patients are different from those studied by Glass *et al.* (1976), and the role of other immunodeficiencies requires further study.

We thank the National Fund for Research into Crippling Disease for their grant to R.J.L.

Reduction of insulin dose on changing diabetic children from standard to monocomponent insulins

N. K. GRIFFIN, M. A. SMITH, AND J. D. BAUM

John Radcliffe Hospital, Oxford

SUMMARY 21 diabetic children requiring >50 units of standard insulin daily were changed to a monocomponent insulin. During the 3 months before the change the insulin dose had risen significantly from a mean of 70 to a mean of 77 units daily. During the 3 months after the change the dose fell significantly to a mean of 53 units daily. This decrease in insulin requirement was associated with a general improvement in diabetic control. This was assessed clinically and measured in 10 children by an analysis of home urine tests and in 8 children by an analysis of 24-hour urine glucose excretion.

There have been significant advances in the manufacture of insulin. This has resulted in solutions that are free from proinsulin, insulin fragments, and other pancreatic contaminants (Schlichtkrull *et al.*, 1972). Such insulins are variously described as proinsulin-free, single peak, or monocomponent insulins, depending on their degree of purity (Root *et al.*, 1972).

The only clear advantage of these insulins is the avoidance or reversal of lipo-atrophy and local reactions at the site of injections (Galloway and Root, 1972; Teuscher, 1975). There have been reports of a reduction of the dose of insulin necessary for the maintenance of diabetic control on changing from standard to purified insulins. Reports of dose reduction has varied from 20 to 50% in different series, consisting mainly of adult diabetics (Bruni *et al.*, 1973; Evans and Smith, 1976; Logie and Stowers, 1976).

We present data on 21 diabetic children requiring >40 units per day of standard insulins in whom a change to monocomponent insulin led to a decrease in insulin requirements and better diabetic control.

Materials and methods

21 children (13 girls and 8 boys) who were unable to achieve satisfactory diabetic control despite high and increasing insulin dosage were changed from standard to monocomponent insulins. The mean age of the group was 7·9 years (range 3–13) and the mean duration of their diabetes from diagnosis was 5·2 years (range 1·5–12). Their treatment before the change is shown in Table 1. All children in this group were changed to a monocomponent porcine insulin (Monotard)* given as a single daily injection. During the 3 months before and 3 months after the change in insulin, diabetic control was measured by an analysis of home urine tests using the Clinitest† 2-drop method (Belmonte *et al.*, 1967), and the 24-hour urinary glucose excretion measured on a collection made at home.

†Ames Company, Slough.

Although the number of tests performed each day by individual children varied, the total number of tests made by these children during the 3 months before the change was 2188 and the total number of tests for the 3 months after the change in insulin was 2089.

Only 8 children were able to provide a 24-hour urine collection for glucose analysis before and after the change. Six of these children were among the 10 who had maintained home urine testing books satisfactorily.

The first 24-hour urine collection for glucose excretion was obtained at a mean time of 6·5 days (range 1–13) before the change to monocomponent insulin. The 2nd 24-hour urine collection was performed 9 weeks (range 3·5–13) after the change to monocomponent insulin.

The glucose content of the 24-hour sample was measured with a glucose analyser which uses glucose oxidase (Analox Instruments). The results are expressed in grams of glucose/24 hours.

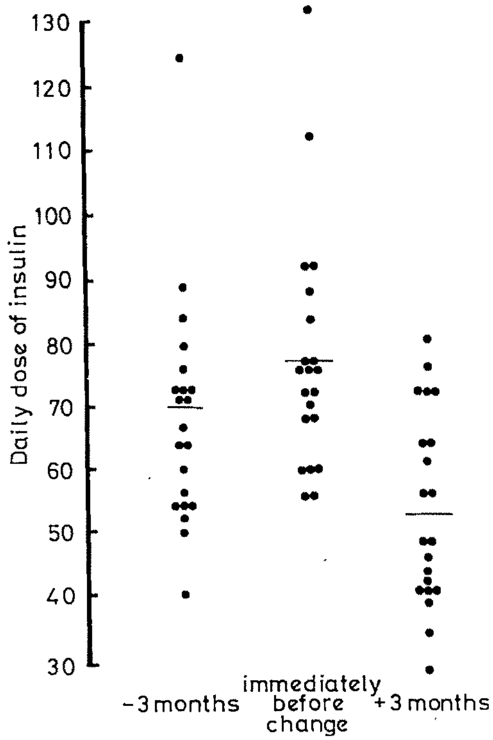

Figure *The total daily dose of insulin for the 21 children rose significantly during the 3 months before the change (paired t test P<0·001) and fell significantly during the 3 months after the change (P<0·001).*

Results

The insulin requirements in the 21 patients 3 months before the change in insulin, at the time of the change, and 3 months after the change, are shown in the Figure. During the 3 months preceding the change the daily dose of insulin rose from a mean of 70 units daily (range 40–124) to a mean of 77 units daily (range 56–132) (P<0·001 using the paired *t* test). In no case had the dose of insulin fallen over this period. During the 3 months after the introduction of monocomponent insulin the mean requirement fell to 53 units daily (range 27–82) (P<0·001 using the paired *t* test). This represents an average fall of 31% in the insulin requirement. In only one child did the insulin requirement actually increase after the change to monocomponent insulin, rising from 60–64 units. The biggest single fall was from 112 to 48 units (a fall of 64%).

An analysis of the home urine tests from 10 children before and after the change in insulin was also made. Taking all the tests available for each child before and after the change and classifying any tests with 0–½% glycosuria as 'good control' and 1–5% glycosuria as 'poor control' a 2 × 2 χ^2 table was drawn up for each patient. Five of the 10 children had significant improvements in their diabetic control with this method of evaluation (P<0·001). One child had a χ^2 value which just fell short of significance. The remaining 4 children had low χ^2 values, indicating no significant improvements in control.

The urine tests for the two 3-month periods were also compared in terms of the number of tests showing zero glycosuria at any time. Using the paired *t* test there was a significant increase in the total number of zero glycosuria tests after the change to monocomponent insulin (P<0·01) (Table 2).

Table 2 *A comparison of the total number of home urine tests using the 2-drop Clinitest method showing zero glycosuria during the 3 months before and 3 months after the change to monocomponent insulin. Using the paired t test there was a significant increase in the total number of zero glycosuria tests (P<0·01).*

The number of zero glycosuria tests before breakfast was considered as an indication of overnight diabetic control. Using the paired *t* test to compare the numbers 3 months before and 3 months after the insulin change there was a significant increase in the number of before-breakfast zero glycosuria tests after the change to monocomponent insulin ($P<0\cdot01$, Table 3).

In 8 children 24-hour urine collections were available as a measure of diabetic control before and after the change (Table 4). The mean glucose excretion before the change was 137 g/24h (range 1–426 g/24 h) which fell to a mean of 88 g/24 h (range 0–237 g/24 h) ($P<0\cdot01$ using the paired *t* test). Only one of these 8 patients showed an increase in glycosuria. The high value for the mean glucose excretion both before and after the change was because 4 of the 8 children had gross glycosuria on standard insulins which fell but failed to achieve reasonable levels by the time of the 2nd urine collection.

Table 3 *Comparison of the number of zero glycosuria tests before breakfast during the 3 months before and after the change to monocomponent insulin. Using the paired t test there was a significant increase in the number of such tests after the change ($P<0\cdot01$).*

Discussion

The introduction of highly purified preparations of insulin represents an advance in the treatment of diabetics with lipo-atrophy at insulin injection sites. Many workers have observed a decrease in the insulin requirements of patients after a change to purified insulins (Evans and Smith, 1976; Logie and Stowers, 1976). This is in accord with the manufacturer's recommendations that, in patients requiring more than 40 units of insulin daily, the dose of insulin should be reduced by 20% at the time of the change (Novo Laboratories Ltd). The mean fall in insulin requirements of our patients was 31% during a 3-month period and some patients required further reductions subsequently. We had made a 10% reduction in the dose at the time of change to monocomponent insulin and subsequent reductions were made by the parents who had been warned of the likelihood of a reduced requirement. The parents judged this dose reduction by frequent home urine tests. In most cases the requirement began to fall after 2 weeks and continued to do so for a further 3–6 weeks. Many children had minor hypoglycaemic symptoms during this period and 2 children had major hypoglycaemic attacks, both suffering from early morning hypoglycaemic convulsions.

Comparative data on the quality of control achieved on changing from conventional to monocomponent insulins has been omitted in previous reports. Our results indicate that control was as good or better in most cases whether assessed clinically or by home urine tests or by 24-hour collections of urine for glucose excretion. Nevertheless the level of diabetic control achieved on monocomponent insulin was certainly not satisfactory at the time of reassessment in at least 4 of the children as judged by the persistently high 24-hour urinary glucose excretion.

Although the change of treatment is associated with the hazards of an uncertain reduction in the dose of insulin required, we do not feel that this constitutes a contraindication to the change provided that this likelihood is appreciated. We feel that all new diabetic children should be started on highly purified insulins and that established diabetic children should be changed on to highly purified insulins because of the reduced incidence of lipo-atrophy (Teuscher, 1975), the reported reduction in insulin antibody levels (Oakley, 1976), and because we believe that insulin should, as far as possible, be free from other protein contaminants as it is to be administered to the child for life.

Dr N. K. Griffin was supported by the Medical Research Fund of the Oxford Clinical School and Mrs A. Smith was in receipt of a grant from the British Diabetic Association.

Interferon synthesis by human colostral leucocytes

J. W. M. LAWTON, K. F. SHORTRIDGE, ROSAMUND L. C. WONG, AND M. H. NG

University of Hong Kong

SUMMARY The antiviral potential of human colostral leucocytes was assessed by their capacity to produce interferon. Leucocytes cultured from colostrum were stimulated by mitogens or Newcastle disease virus (NDV) to produce interferon which, by metabolic and physicochemical criteria, corresponded to normal human leucocyte interferon. Prepartum cells produced higher levels than postpartum cells. Colostral cells were less efficient producers than blood leucocytes.

Human colostrum and breast milk contain inhibitors for a variety of viruses (Sabin and Fieldsteel, 1962; Shortridge *et al.*, 1974; Matthews *et al.*, 1976). The presence of interferon in human colostrum or milk has not been conclusively demonstrated, although colostral leucocytes are known to be able to synthesise interferon-like material in response to stimulation (Emödi and Just, 1974; Lawton and Shortridge, 1977).

In view of the current interest in the function of these cells and their possible contribution to neonatal defences in breast feeding, we have investigated further the capacity of colostral cells to synthesise interferon when stimulated by mitogens and inactivated NDV. We also report the results of our characterisation of this substance.

Materials and methods

Preparation and culture of colostral cells. Colostrum samples were obtained from 26 women, mainly Chinese, by manual expression into sterile plastic universal bottles. 11 samples were prepartum and 15 were 2 to 5 days postpartum. Samples were diluted 1:1 in Hank's balanced salt solution (HBSS), centrifuged at 110 × *g* for 10 min and the pellet washed twice in HBSS before counting the cells in a haemocytometer. Total cell counts in colostrum ranged from 0·6 to 11 × 10^9/l (600 to 11 000/mm^3) mean 3·37 × 10^9/l (3370/mm^3). Differential counts were performed on stained cytocentrifuge preparations; macrophages made up 11–94% (mean 57%), polymorphonuclear leucocytes (PMNs) 2–87% (mean 33%), and lymphocytes 1–39% (mean 9·6%).

After counting, the cells were resuspended at a concentration of 2 × 10^9 cells/l (2000/mm^3) in leucocyte growth medium (LGM) comprising RPMI-1640 (Gibco) supplemented with 20% heat-inactivated human AB serum, glutamine 2 mmol/l, penicillin 100 U/ml, and streptomycin 100 µg/ml. One ml volume of cell suspension was dispensed into Nunc tissue culture tubes; the total number of cells obtained from the colostrum sample (usually about 15 × 10^9/l (15 000/mm^3)) limited the number of replicate cultures that could be performed. Mitogens known to stimulate leucocyte interferon synthesis were added to the cultures in predetermined optimal doses; PHA-P (Difco) 5 µl/ml, Conconavolin-A (Sigma) 40 µg/ml. Cells were also preincubated for 30 min with an optimal dilution of a lentogenic (avirulent) strain of NDV (D2/75) and then washed 3 times before resuspending in LGM for culture. Each experiment included an unstimulated control culture. Cultures were incubated at 37°C for 72 hours. The supernatants were harvested and replicate supernatants pooled before being assayed for interferon activity. Supernatants were routinely stored frozen at −20°C, but for periods of less than 24 hours they were held at 4°C.

Interferon assay. The assay was based on that of Havell and Vilček (1972) using human diploid foreskin fibroblasts in Linbro micro T/C plates. Fibroblasts were challenged with vesicular stomatitis virus (VSV) after 24-hour exposure to culture supernatants and the titre of interferon was expressed as the reciprocal of the highest protective dilution. A standard interferon preparation (13 000 NIH units/

ml) consistently gave a titre of 50 000. Samples were titred at trebling dilutions beginning at 1/5 and assayed in duplicate.

Dialysis of samples before assay did not alter the interferon titre but it did reduce the cytotoxic effect on fibroblasts which was sometimes observed at low dilutions (1/5 or 1/15). Therefore predialysis of samples at pH 2 was adopted as standard procedure (see below, acid dialysis). Samples containing Con-A tended to be more toxic to the fibroblasts at low dilutions and this effect was not removed by dialysis. Consequently Con-A was often omitted and Con-A supernatants were not used in the characterisation studies even though it tended to induce higher interferon levels than PHA or NDV.

Comparison of colostral cells and autologous blood leucocytes. In 7 cases autologous blood leucocytes were cultured in parallel with the colostral cells to compare their capacities to synthesise interferon-like substances *in vitro*.

Blood lymphocytes were separated from heparinised blood over Ficoll/Hypaque, washed 3 times in BSS, counted and resuspended in LGM at 2 × 10^9 cells/l (2000/mm^3). The suspensions contained 5–15% monocytes. The blood mononuclears were stimulated with PHA and NDV as described for colostral cells. After 72 hours' incubation the supernatant was harvested and assayed for interferon activity.

Characterisation studies. High titre supernatants of PHA- or NDV-stimulated cultures were pooled and studied as follows:

Metabolic characterisation
This was based on the fact that the protective effect of interferon requires intact mechanisms of RNA and protein synthesis in the cells on which protection is to be conferred (Ng and Vilček, 1972).

To inhibit RNA synthesis fibroblasts were pretreated with actinomycin D (0·5 and 1·0 μg/ml in culture medium) for 30 min at 37°C then washed 3 times in HBSS before adding the pooled supernatant. To inhibit protein synthesis cycloheximide was diluted in culture medium to 100 μg/ml and this medium was used as diluent for the pooled supernatant. Cells exposed to cycloheximide were washed 3 times in HBSS before virus challenge. Supernatant was also assayed on control cells not exposed to metabolic inhibitor. Each group included appropriate positive and negative controls for virus cytopathic effect.

Physiocochemical characterisation
Supernatant aliquots were treated as described below before assay.

Acid dialysis. Supernatants were dialysed against 0·1 mol/l KCl, pH 2, at 4°C for 18 hours, then against phosphate buffered saline (PBS), pH 7·4, for 4 hours. Control supernatants were dialysed for 22 hours against PBS only.

Freeze-thaw, heat, and trypsinisation. Respective aliquots were frozen to −70°C and thawed 5 times, heated to 56°C for 30 min, or incubated in the presence of trypsin (1·25 mg/ml) at 37°C for 5 hours. A control aliquot was kept at 4°C.

Detection of sialic acid residues. Pooled supernatant of known titre was applied to a column of immobilised neuraminidase at pH 4·5. The column was developed by elution with 0·1 mol/l/acetate buffer in 0·5 mol/l NaCl, pH 4·5, followed by 0·1 mol/l bicarbonate in 0·5 mol/l NaCl, pH 9·0. The eluted protein peaks (0D 280 nm) were collected and tested for interferon activity (Fung and Ng, 1978).

In the interferon characterisation experiments supernatants were titred at trebling dilutions.

Results

Table 1 shows the geometric mean titres of interferon in the colostral cell cultures. Two PHA supernatants (>135) were not titred to the endpoint; these were taken as 135 and all negative samples (<5) were taken as 1 for purposes of calculation. The highest interferon titre obtained was 640 in a Con-A stimulated culture from a prepartum sample. The combined results (pre- and postpartum) show that Con-A gave the highest mean interferon activity, while NDV, although less efficient than Con-A, was a more efficient inducer than PHA. All unstimulated control cultures were negative for interferon activity (titre <5).

Prepartum colostral cells produced higher interferon levels than postpartum cells; this was so for

Table 1 *Interferon activity in colostral cell culture supernatants*

	PHA stimulated	*Con-A stimulated*	*NDV stimulated*	**All inducers*
Prepartum	11 (1–320) n = 11	59 (1–640) n = 3	38 (15–135) n = 7	21 (1–640) n = 21
Postpartum	7·6 (1–135) n = 15	24 (1–135) n = 6	12 (1–45) n = 8	11 (1–135) n = 29
All cultures (pre- and postpartum)	9·7 (1–320) n = 26	32 (1–640) n = 9	19 (1–135) n = 15	

The results are expressed as geometric mean titres of 72-hour culture supernatants with titre ranges in parentheses. Differences between mean titres of pre- and postpartum cultures did not reach significance at the 5% level (2-tailed Student's *t* test). Unstimulated control cultures were negative (titre <5) in all experiments.
*Pooled data for the 3 inducers.

each inducer but even when data were pooled (Table 1) the difference was not significant at the 5% level ($0{\cdot}15>P>0{\cdot}1$). This difference could not be explained by the relative proportions of cell types in the cultures; the mean percentages of macrophages, lymphocytes, and PMNs in prepartum and postpartum colostrum were very similar and the overall data showed no clear correlation between interferon titres and the proportions of cell types in the original culture inocula.

Colostral cells and autologous blood leucocytes. The geometric mean titres of interferon from these paired cultures are set out in Table 2. The capacity of blood mononuclears to synthesise interferon in response to NDV stimulation was significantly higher than that of colostral cells ($P<0{\cdot}025$), whereas the difference in response to PHA did not reach a level of significance ($P>0{\cdot}15$).

Table 2 also shows that NDV was clearly a more efficient inducer of interferon in blood leucocytes than was PHA (ratio, 8·5:1), whereas colostral cells demonstrated little difference in response to these two inducers.

Interferon characterisation. The results of the characterisation studies are summarised in Table 3. Inhibitors of RNA and protein synthesis both abrogated the protection of fibroblasts by the culture supernatants, consistent with the protective effect being due to interferon.

Activity was not dialysable; it was stable at pH 2 and destroyed by trypsin. PHA-induced activity was stable to freeze–thaw and relatively heat stable. On the other hand, NDV-induced activity was relatively freeze–thaw stable and heat labile.

Table 2 *Interferon activity in colostral cell and autologous blood leucocyte cultures*

	PHA-stimulated		*NDV-stimulated*	
Colostral cells	16 (1–135)	$P>0{\cdot}15$ (n = 7)	18 (5–45)	$P<0{\cdot}025$ (n = 6)
Autologous blood leucocytes	10 (1–45)		85 (15–415)	

The results are expressed as geometric mean titres of 72-hour culture supernatants with titre ranges in parentheses. P values were computed by the Student's *t* test for correlated data. Unstimulated control cultures were negative (titre <5) in all experiments.

Interferon activity induced by NDV bound to a column of immobilised neuraminidase at acid pH via its N-acetyl-neuraminic acid residues and could be recovered essentially without loss of activity by elution at pH 9·0.

Discussion

Recent studies have shown that leucocytes in colostrum may play an important role in transferring specific and nonspecific host resistance factors to the neonate (Murillo and Goldman, 1970; Ahlstedt *et al.*, 1975; Parmely *et al.*, 1976; Pitt *et al.*, 1977; Schlesinger and Covelli, 1977). Our results confirm that colostral leucocytes can synthesise interferon under appropriate conditions and that their capacity to do so is comparable with that of blood leucocytes (Emödi and Just, 1974).

Interferon protects a cell by first inducing the synthesis of an antiviral protein (Joklik, 1977) and this process is dependent on intact mechanisms of RNA and protein synthesis (Ng and Vilček, 1972). It was found that the antiviral effect observed in our experiments was dependent on (1) pretreatment of cultures with supernatant, and (2) intact macromolecular synthesis of the fibroblasts. It was further shown that the antiviral substance was nondialysable, resistant to treatment with acid, stable to freeze–thaw, destroyed by trypsin, and it appeared to have sialic acid residues which bound it to immobilised neuraminidase. These are all known properties of interferon.

Surprisingly, this interferon was unlike classical human leucocyte interferon (type I) in being relatively heat labile. Haahr *et al.* (1976) showed that the presence of fully differentiated macrophages resulted in the production of heat-labile (type II) interferon by human lymphocytes. Therefore the high proportion of mature macrophages in colostral leucocyte cultures may account for heat-labile interferon synthesis. Because our colostral cells contained a mixture of lymphocytes (usually <10%) and macrophages, it is difficult to draw any conclusions about

the principal cell of origin of the interferon activity. Human interferon is known to be heterogeneous with respect to the cell of origin and to the type of inducer (Vilček *et al.*, 1977); it is likely, therefore, that the active material in our cultures represented a mixture of 'interferons'.

It is of interest that prepartum colostrum leucocytes showed a greater capacity to produce interferon than did postpartum cells. This difference could not be related to the very small differences in proportions of cell types in the cultures; the reason for it remains unknown.

Emödi and Just (1974) and Matthews *et al.* (1976) were unable to detect free interferon-like activity in human colostrum or breast milk. We have been able to detect interferon-like activity in a small proportion of the samples of colostrum and breast milk which we have tested (unpublished observations) and work is in progress to characterise it. It is not yet clear whether this activity is related to infection in the mother.

The important implication of our findings is that since colostral leucocytes under appropriate conditions can produce interferon, they may thereby confer on the suckling infant protection against viral infection.

We thank Miss Chan Kwan Lai and Miss L. Y. Hu for their excellent technical assistance.

Duodenal bile acids in infants with protracted diarrhoea

D. N. CHALLACOMBE, G. A. BROWN, AND SUSAN EDKINS

Institute of Child Health, University of Birmingham

SUMMARY Bile acids were estimated in the duodenum of infants with protracted diarrhoea and compared with those in a control group. Significantly lower levels of total bile acids were found in infants with protracted diarrhoea, a finding which may be due to ileal dysfunction. Low concentrations of total bile acids may contribute to the poor nutritional state of these patients by impairing the normal digestion and absorption of dietary fat and fat-soluble vitamins. The absence of deconjugated bile acids in the duodenal juice of most infants with protracted diarrhoea suggests that they do not contribute significantly to the pathophysiology of this disorder.

Protracted diarrhoea of infancy is a severe and debilitating disorder, characterised by the passage of at least 4 loose stools a day for more than 2 weeks. In some infants protracted diarrhoea is secondary to recognised gastrointestinal diseases (Larcher *et al.*, 1977), while in others the pathogenesis remains unknown. The patients become dehydrated and malnourished due to persistent fluid loss and to difficulty in maintaining an adequate oral intake of food. Impaired digestion and absorption, resulting from a damaged small intestinal mucosa, also contribute to the poor nutritional state. As recovery of small intestinal mucosal function may be delayed by malnutrition, a vicious cycle of events occurs which perpetuates the clinical problem, and intravenous nutrition may be needed to sustain life.

Bile acid studies on infants with protracted diarrhoea have shown two principal abnormalities, either of which could contribute to the pathophysiology of this disorder. Deconjugated bile acids were detected in the duodenal juice of some infants (Gracey *et al.*, 1969), while in experimental animals the same bile acids had cytopathic effects on the small intestinal mucosa (Dawson and Isselbacher, 1960), and inhibited the absorption of water, electrolytes, and monosaccharides from the lumen of the small intestine (Gracey *et al.*, 1971; Harries and Sladen, 1972). Increased faecal excretion of bile acids has also been shown in infants with protracted diarrhoea (Balistreri *et al.*, 1977). If the loss is prolonged, it may reduce the size of the bile acid pool and lower the concentration of bile acids in the small intestine. As bile acids are essential for the optimal absorption of dietary fat and fat-soluble vitamins, a fall in concentrations below the level at which micelle formation occurs in the small intestine might further compromise the poor nutritional state of the patient. Bile acids in the duodenum of a control group of infants (group A) were therefore compared with those in a group of infants with protracted diarrhoea (group B).

Materials and methods

Patients. The infants were divided into two groups (Table 1). Infants with protracted diarrhoea (group

B) had been passing at least 4 loose stools daily for more than 2 weeks, without the isolation of known enteropathogenic bacteria. Stools were tested for the presence of reducing substances using Clinitest tablets (Kerry and Anderson, 1964), and significant amounts (>0·5%) were detected in 3 of them. The presence of glucose was confirmed by paper chromatography in 2 patients and lactose in one. All the infants in the control group (group A) needed tube feeding as a normal part of their medical care, and none had diarrhoea. As concentrations of duodenal bile acids have been shown to increase with age in early infancy (Challacombe *et al.*, 1975), these infants were of approximately similar ages as those in group B.

Sampling regimen. Duodenal juice was obtained by the use of a long polyethylene feeding catheter (Argyl, 5 FG, 91 cm), weighted with a gold bead (Rhea and Kilby, 1970). The distal end of the tube was allowed to pass into the duodenum by normal peristalsis and its position in the 2nd to 4th part of the duodenum was confirmed by screening. The first sample of duodenal juice aspirated was discarded to exclude contamination by gastric juice and the 2nd sample was placed in a sterile container and stored at −20°C until analysed. Samples were taken 2 hours after a full cream cows' milk formula feed in group A and 2 hours after a 5% glucose feed in group B. The absence of significant differences in duodenal bile acid concentrations in infants 2 hours after either type of feed has been previously demonstrated (Challacombe *et al.*, 1975).

Bile acid analysis. Bile acids were estimated using sulphuric acid fluorescence after separation by thin layer chromatography (Panveliwalla *et al.*, 1970). Total and individual bile acids were measured in samples of duodenal bile from both groups of infants. Separate estimates of the individual taurine and glycine conjugated dihydroxy bile acids were not made because it was not possible to separate them by the chromatographic method.

Results

The results of bile acid analyses are shown in Table 2. The difference between mean values of total bile acids, taurine, and glycine conjugates, and individual bile acids in group A and group B were examined for statistical significance using Student's *t* test. Differences were regarded as significant when P values were $<0\cdot05$.

Concentrations of total bile acids were significantly lower in infants in group B ($P<0\cdot01$). This finding was mainly due to lower mean concentrations of taurocholic ($P<0\cdot01$) and glycocholic acids ($P<0\cdot05$). Ratios of total glycine conjugates to total

Conversion: SI to traditional units—Taurocholic acid: 1 mmol/l ≈ 51·5 mg/100 ml. Taurine conjugated dihydroxy bile acids: 1 mmol/l ≈ 49·9 mg/100 ml. Taurolithocholic acid: 1 mmol/l ≈ 43·8 mg/100 ml. Glycocholic acid: 1 mmol/l ≈ 46·5 mg/100 ml. Glycine conjugated dihydroxy bile acids: 1 mmol/l ≈ 44·9 mg/100 ml.

taurine conjugates (G/T) were not significantly different in the two groups. Mean concentrations of taurine conjugated dihydroxy bile acids, glycine conjugated dihydroxy bile acids, and taurolithocholic acid were also not significantly different. In group B taurocholic acid was present in 4 out of 5, taurolithocholic acid in 3 out of 5, and glycine conjugated dihydroxy bile acids in 3 out of 5 infants. In group A all bile acids were present with the exception of taurolithocholic acid which was not detected in one patient. Deconjugated bile acids were not detected in infants in group A, but cholic acid (0·13 mmol/l; 5·3 mg/100 ml), chenodeoxycholic acid (0·57 mmol/l; 22·3 mg/100 ml), and lithocholic acid (0·25 mmol/l; 9·4 mg/100 ml) were found in the duodenal juice of one infant in group B who had secondary lactose intolerance. In this infant, who has been previously reported (Challacombe *et al.*, 1974a), *Bacteroides* sp. (obligate anaerobes with known bile acid deconjugating properties *in vitro*) were isolated from the duodenal juice.

Discussion

Concentrations of total bile acids were significantly lower in the duodenum of infants in group B compared with group A. Morphological and functional changes in the bowel may interrupt the enterohepatic circulation of bile acids leading to increased bile acid excretion in the faeces. The liver initially compensates for the increased faecal loss by increased synthesis, but eventually synthesis is inadequate, leading to a depleted bile acid pool and to low levels of bile acids in the duodenum. There is some experimental evidence in favour of this proposed mechanism. The oral or intravenous administration of radioactively-labelled bile acids to adults with diffuse ileal disease leads to rapid excretion of the radioactive label in the faeces (Meihoff and Kern, 1968). Oral administration of C^{14}-cholic acid to infants with ileal resections and to infants with protracted diarrhoea also results in increased faecal excretion of this label (Balistreri *et al.*, 1977). The presence of ileal dysfunction in protracted diarrhoea is further suggested by abnormal Schilling tests for vitamin B12 absorption (Balistreri *et al.*, 1977). Impaired ileal function may be the result of associated mucosal damage. Severe mucosal changes have been reported in the upper small intestine (Greene *et al.*, 1975) and these may be sufficiently extensive to involve the terminal ileum where most bile acid reabsorption should occur. Ileal dysfunction may also contribute to the protracted diarrhoea in these patients, as excessive amounts of dihydroxy bile acids reaching the colon have been shown to provoke excessive water secretion by the colonic mucosa (Mekhjian *et al.*, 1971).

A higher ratio of glycine to taurine conjugates in duodenal bile is usually present in adults with terminal ileal disorders (Heaton *et al.*, 1968), a finding which may be due to the relative scarcity of taurine or of its precursor cysteine, in the face of an increased demand for bile acid conjugation. Mean values of the glycine/taurine ratio were not significantly raised in patients with protracted diarrhoea compared with the controls. As bile acids are mainly conjugated with taurine in early infancy, failure to demonstrate consistently raised glycine/taurine ratios in patients with protracted diarrhoea may be due to an increased availability of taurine for conjugation.

Trihydroxy bile acid concentrations were significantly lower in infants in group B compared with group A, and mean concentrations of dihydroxy bile acids were also low, but the values did not reach statistical significance. In adults with ileal resections the absorption of both dihydroxy and trihydroxy bile acids has been shown to be equally impaired (Low-Beer *et al.*, 1974). Although ileal dysfunction may be one explanation for the bile acid findings reported in protracted diarrhoea, further study of the enterohepatic circulation and faecal excretion of bile acids in this disorder will be necessary. Bacterial overgrowth in the upper small intestine (Gracey and Stone, 1972; Challacombe *et al.*, 1974b), a rapid small intestinal transit time, or impaired synthesis of bile acids by the liver due to malnutrition, could each influence bile acid metabolism in infants with protracted diarrhoea.

The deconjugated bile acids, deoxycholic and chenodeoxycholic acids, have been shown to have cytopathic and metabolic-inhibitory effects on the small intestine of experimental animals (Dawson and Isselbacher, 1960; Low-Beer *et al.*, 1970; Gracey *et al.*, 1971; Harries and Sladen, 1972), and these bile acids could have similar effects in patients with protracted diarrhoea and monosaccharide malabsorption (Gracey *et al.*, 1969). Cholic, chenodeoxycholic, and lithocholic acids were detected in small quantities in only one infant with protracted diarrhoea, an infant who was also intolerant of oral lactose. These findings suggest that deconjugated bile acids were not important in the pathophysiology of protracted diarrhoea in our patients, but samples were taken from a single site only in the duodenum, and sampling from other sites will be necessary before the contribution of deconjugated bile acids can be fully evaluated. Concentrations of total bile acids in the duodenum of 4 of the 5 infants in group B were below a level of 4 mmol/l. Badley *et al.* (1969) have shown that total bile acid concentrations in the upper small intestine should exceed this value for optimal fat absorption to occur. The digestion and absorption of dietary fat and fat-soluble vitamins may therefore be impaired in patients with protracted diarrhoea, and absorption and nutrition may be improved by the use of medium chain triglycerides, which are well absorbed in the absence of bile acids.

We are grateful for the advice and assistance given to us by Professor Charlotte M. Anderson. D.N.C. was supported by a grant from the Endowment Fund of the United Birmingham Hospitals and S.E. from the Medical Research Council.

Familial partial trisomy of the long arm of chromosome 3 (3q)

CLAUDINE FEAR AND ALLEN BRIGGS

Paediatric Research Unit, Prince Philip Research Laboratories, and Department of Paediatrics, Guy's Hospital, London

SUMMARY A case of partial trisomy of the long arm of chromosome 3 (3q21→qter) is described. The clinical findings are compared with those in 5 previously reported cases. There is hirsutism and characteristic facial dysmorphism, the common features of which are a square-shaped face, prominent nasal bridge, everted nostrils, hypertelorism, and palate abnormalities; occurring less often are abnormalities of vertebrae, thorax, and digits, or cardiovascular, urinogenital, and central nervous system. New features noted in this present case are absence of right eye from orbit and spina bifida. The spectrum of this syndrome is discussed, with possible relation to the degree of trisomy. The present case is the 6th to be reported with partial trisomy of the long arm of chromosome 3.

Case report

The propositus (Fig. 1) was the result of a 3rd pregnancy of the mother; she had had 2 phenotypically normal children from a previous marriage. The pregnancy was noted for small fetal size, lack of intrauterine movements, and recurrent small antipartum haemorrhages. Urinary oestriol excretion was low throughout the pregnancy. The child was delivered by emergency caesarean section when the mother presented in labour with a fetal heart rate of 80.

The child, a girl, with multiple congenital anomalies, died soon after delivery. Clinical features included: a square-shaped face; wide nasal bridge and everted nostrils; small malformed and malpositioned ears; absence of right eye; high arched palate; a short webbed neck; clinodactyly of the 5th fingers; lumbar meningomyelocele with congenital dislocation of both hips, and bilateral talipes equinovarus. *X*-ray of the chest showed hypoplasia of the right first rib.

Necropsy (Guy's Hospital, no. 362/76) (Dr J. Heaton) showed absence of the roof of the right orbit and the dysplastic right eye was found in the anterior cranial fossa. Large anterior and posterior sagittal fontanelles separated the bones of the vault of the skull. The brain (250 g) was sectioned to show diffuse dilatation of the ventricular system consistent with internal hydrocephalus. There was a large atrial septal defect. The left kidney and part of the right kidney showed pin-point sized cysts which were visible both externally and on the cut surfaces. There were also bilateral double ureters draining the cystic dysplastic kidneys; on the left side both were severely dilated and kinked; on the right only one was dilated.

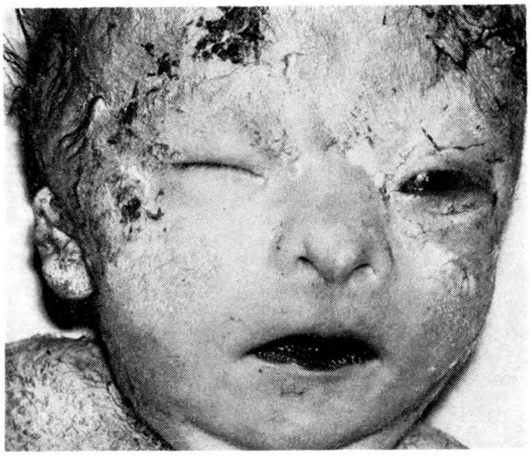

Fig. 1 *The propositus, note square-shaped face, malformed ears, absence of right eye.*

Chromosome studies. Chromosomes prepared from cultured skin fibroblasts and lymphocytes from the

ALLEN BRIGGS, senior registrar

propositus were either banded with trypsin and stained with Geimsa (G bands) or stained with quinacrine mustard to give Q bands. Analysis showed additional chromosomal material on the long arms of no. 13 (Fig. 2c). Subsequent studies of the mother's chromosomes showed a balanced translocation between the long arms of nos 3 and 13 (Fig. 2a), which may be expressed as: 46,XX,t (3;13) (q21;q34), and the child's unbalanced chromosome constitution as: 46,XX,der(13), t(3;13) (q21;q34) mat. The propositus therefore had 2 normal chromosomes no. 3 and an abnormal no. 13 to which a large additional segment of the long arm of no. 3 was attached, with slight loss of the terminal region of 13q.

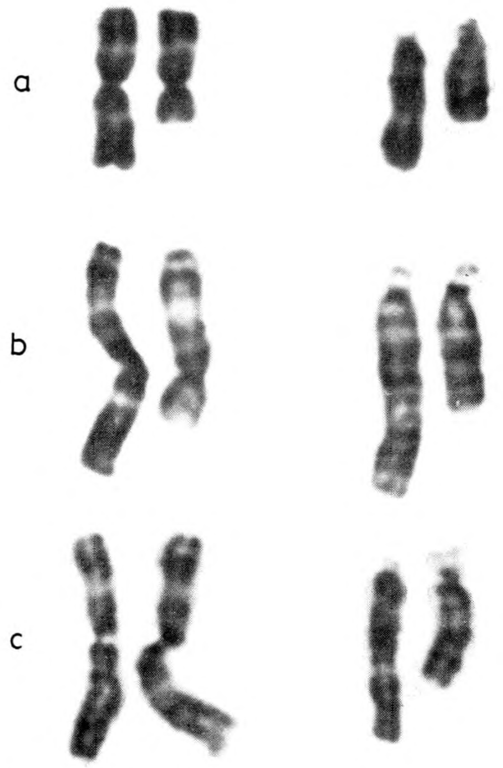

Fig. 2 (*a*) *balanced chromosomes mother t(3;13) (q21;q34);* (*b*) *balanced chromosomes daughter t(3;13) (q21;q34);* (*c*) *unbalanced chromosomes propositus der(13)t(3;13) (q21;q34)mat.*

One of two sisters carried the translocation in the balanced form (Fig. 2b) and the other sister had a normal female chromosome complement.

The maternal great-grandparents (Fig. 3) (I,3 and I,4) had 17 children, 10 of whom died neonatally. The maternal grandmother (II,9) had 3 miscarriages out of 7 pregnancies, while the maternal aunt (III,4) had 3 miscarriages and one neonatal death from 4 pregnancies and was then sterilised. The index family has two phenotypically normal children and the propositus.

In three generations about half the number of babies known to have been conceived had survived pregnancy. The losses were attributable to miscarriage and neonatal death and it is probable that most were the result of the translocation in an unbalanced form. However, there are no details of these except that at least 6 were miscarriages.

Discussion

Table 1 lists the features of 5 known cases of partial trisomy 3q and a 6th case (Clarke *et al.*, 1964) in which there was no banding information but as the clinical features were similar it is felt that there is justification for its inclusion. All have in common the square-shaped face with prominent nasal bridge

everted nostrils, hirsutism, hypertelorism, and palate abnormalities. Other features present in decreasing frequency are micrognathia, malformed low-set ears, clinodactyly, foot abnormalities, webbed neck, thoracic and vertebral defects, and urinogenital abnormalities. Features noted in isolation include deafness, cataracts, abnormal thumb insertion, syndactyly, short 5th metacarpal (Schwanitz *et al.*, 1977). Clarke *et al.* (1964) and Schwanitz *et al.* (1977) also noted hyperextensible joints and bilateral single palmar creases. Features in the present case not previously described are microphthalmia and meningomyelocele.

In these 6 cases of partial trisomy 3q, 3 died neonatally (present case; Hirschhorn *et al.*, 1973; Chiyo *et al.*, 1976) and 3 survived into childhood (Clarke *et al.*, 1964; Schwanitz *et al.*, 1977). The survivors did not have the gross abnormalities of heart and brain which were incompatible with life but they all had hypotonia, epilepsy, and moderate mental retardation.

The reported cases, and our own, had unbalanced chromosome abnormalities which resulted from structural anomalies in a carrier parent (5 maternal, 1 paternal) (Table 2). An inversion was present in one (Hirschhorn *et al.*, 1973) and the remaining 5 were the result of reciprocal translocations involving 3q with other chromosomes. Nevertheless, we note that 3 cases have similar break points (3q21) (Hirschhorn *et al.*, 1973; Chiyo *et al.*, 1976; present case). It may be significant that they have a similar clinical pattern. Two of the milder cases, brothers, had a more distal break point (3q25) and are therefore trisomic for a smaller portion of 3q (Schwanitz *et al.*, 1977). In the 6th case (Clarke *et al.*, 1964) the actual break points were not established.

The only important factor is the duplication of 3q; the deficiencies of the other chromosomes are slight, since only their terminal bands are involved, present case (13q34), Chiyo (2p25), and Schwanitz (the heterochromatic regions of 22p, which are generally thought to be genetically inert). In Hirschhorn's case the 3 alone is involved and the details of the break points in Clarke's case are not known.

From such a small group of cases the range of abnormalities associated with partial trisomy 3q cannot be defined. The features common to these cases provide a characteristic facial appearance by which others may be suspected, but a chromosomal diagnosis should always be established.

We thank Dr Leo Stimmler, Department of Paediatrics, Guy's Hospital, for referral of the propositus, and Dorothy Garrett for technical assistance.

This work was partly supported by the Spastics Society and the Department of Health and Social Security.

Hepatic dysfunction in childhood malaria

ASHOK PATWARI, S. ANEJA, A. M. BERRY, AND SHANTI GHOSH

Safdarjang Hospital, New Delhi

SUMMARY Hepatic function of 80 children aged under 3 years with *Plasmodium vivax* malaria were studied during the acute attack and 6 weeks after antimalarial treatment. Raised levels of serum aspartate transaminase (serum AST; SGOT), serum alanine transaminase (serum ALT; SGPT), and alkaline phosphatase were observed in 68%, 39%, and 46% of cases respectively. AST levels were higher than ALT ones and the mean level of both enzymes was much higher in patients with hepatomegaly. The hepatic dysfunction which these observations reflect is transient, as these enzymes were found to be at their normal levels 6 weeks after treatment. A transient derangement of liver function is thus a common feature of childhood malaria, and hepatic dysfunction takes place to a significant degree even in *P. vivax* malaria.

Malaria can bring about the inhibition of certain liver functions even in the absence of normal clinical signs of hepatic insufficiency. While normal liver functions may be restored after termination of the malarial attack, long continued low-grade malarial infection can cause permanent liver damage (Maegraith, 1948). Liver function has been studied in adults suffering from malaria and in experimental animals. Most studies on liver function have been on *Plasmodium falciparum* malaria, and hepatic dysfunction in *Plasmodium vivax* malaria has received little attention.

Material and methods

Children attending the outpatient department and those admitted to paediatric wards of this hospital in whom a diagnosis of malaria was confirmed by the presence of malarial parasite in the blood were studied. A detailed history was taken and a clinical examination given and then the following investigations were undertaken: serum bilirubin, serum aspartate transaminase (serum AST; SGOT) and alanine transaminase (serum ALT; SGPT), and alkaline phosphatase. Urine was examined for urobilinogen, bile salts, and bile pigments. Children with jaundice were further investigated for red blood cell morphology, reticulocyte count, and Coombs's test.

Observations. 80 children from one month to 3 years of age were studied. *P. vivax* was causative in all. Fever was the chief presenting complaint. Clinically, splenomegaly was present in 83% and hepatomegaly in 68% of cases. Jaundice was observed in only 8·7% of cases; all the jaundiced patients had hepatomegaly.

Out of 54 cases *with hepatomegaly* (group 1) AST was increased in 69%, ALT in 37%, and alkaline phosphatase levels were high in 50%. In 26 cases *without hepatomegaly* (group 2), 65% had increased levels of AST, 38% increased ALT, and 38% had increased alkaline phosphatase levels (Table 1).

Serum bilirubin was increased in 7 cases in group 1. Jaundice in these cases seemed to be hepatocellular in 3, haemolytic in 2, and obstructive in 2 (Table 2).

Urine examination was essentially normal in all except one patient whose urine contained bilirubin (Table 2).

Follow-up showed that 6 weeks after the malarial attack, liver enlargement had diminished, jaundice

had disappeared, and serum enzymes and bilirubin levels had returned to normal in all cases.

Discussion

Symptoms of disturbed liver function may appear during the course of all forms of malaria (Kern and Norris, 1944), the more serious disturbances being reported in *P. falciparum* infection. The pathogenesis of hepatic dysfunction in malaria is not understood and is probably multifactoral. Liver functions in malaria were studied as early as 1923 by MacCormac and Dodds, who observed an increase in urinary urobilin and urobilinogen, and similar observations were later made by Wallace and Diamond (1925), and Fredricks and Hoffbauer (1945). Increased excretion of urobilin and reduction in excretion of azorubin-S was also noted in *acute* malaria (Maegraith, 1948). Russel (1952) found reduction in total plasma proteins and albumin fraction. Serum α_1-globulin may rise and α_2-globulin fall (Tella and Maegraith, 1965). Serum fibrinogen increases in many cases (Devakul *et al.*, 1966). Increase in plasma bilirubin (Woodruff, 1974), serum glutamic oxalacetic, and pyruvic transaminases (Sadun *et al.*, 1966; Deller *et al.*, 1967) have also been reported. Laevulose tolerance tests performed on malarial patients have suggested hepatic dysfunction (Sinton and Hughes, 1924). Lippincott *et al.* (1945) carried out liver function tests in cases of *chronic* relapsing *P. vivax* malaria and found transient derangement of liver functions in some cases.

In the present study AST and ALT levels were found to be increased in most patients (Table 1), consistent with the observations of Deller *et al.* (1967). Mean levels of AST were higher than ALT although a greater increase in ALT than AST was reported by Sadun *et al.* (1966). AST was increased in 69% cases in group 1, and it is interesting that almost the same percentages of cases (65%) in group 2 also had higher levels of AST. Similar observations were made with ALT levels in the two groups (Table 1). However, within the two groups the levels of these enzymes were higher in the group with hepatomegaly. In half the cases in group 1 alkaline phosphatase levels were increased compared with 38% of cases in group 2 (Table 1) and in these patients the levels of AST and ALT were also raised.

Of 54 patients with disordered liver functions, in 35 the nutritional status was between the 25th and 50th centiles, 16 between the 3rd and 25th centiles, and only 3 cases were below the 3rd centile of Harvard standards. To what extent the nutritional status of these children affected their hepatic function is difficult to know, but as only 6% of cases had severe malnutrition the hepatic dysfunction can be attributed to the acute malaria.

We conclude that mild and transient hepatic dysfunction with increased levels of serum enzymes is a common feature of an acute attack of malaria, with or without hepatomegaly. Jaundice, although an uncommon feature, is associated with more severe hepatocellular damage, while obstructive jaundice seems to imply a more severe hepatic dysfunction.

We are grateful to the Medical Superintendent of Safdarjang Hospital for permitting this study.

Short reports

Familial occurrence of omphalocele suggesting sex-linked inheritance

S. HAVALAD, H. NOBLETT, AND B. D. SPEIDEL

Department of Paediatrics, Southmead General Hospital, Bristol

SUMMARY A family is described in which 4 males in two generations had omphalocele. There was no case of omphalocele in any of the women. It is suggested that the mode of inheritance could be a sex-linked recessive trait.

The occurrence of omphalocele in siblings is rare (McKeown *et al.*, 1953; Irving, 1967; Rothemberg and Barnet, 1974; Rott and Truckenbrodt, 1974) and there is only one report of the presence of this malformation in two generations of a family (Osuna and Lindham, 1976). We report a family in which 4 cases of omphalocele occurred in two generations. Only males were affected, suggesting a sex-linked mode of inheritance.

Case reports

Case 1. (Figure). A male term infant was born to an 18-year-old primigravida, labour was induced because of hypertension. The infant, who weighed 3490 g, had an omphalocele of 4·5 cm in diameter and the sac contained liver and small intestines. A primary closure was done at age 8 hours. He needed to be digitalised for congestive cardiac failure due to a ventricular septal defect which has since closed spontaneously. He did not have macroglossia nor did he develop hypoglycaemia. He is now 36 months old and has developed normally.

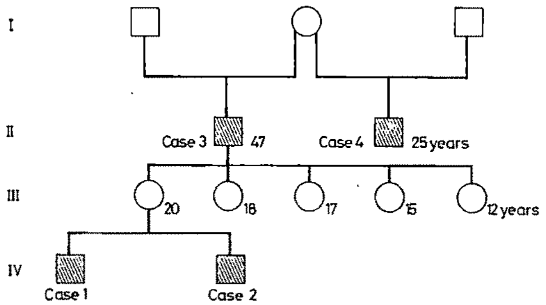

Figure *Family tree showing distribution of omphalocele in male siblings only.*

Case 2. A younger brother of Case 1, was born after a gestation of 40 weeks. The pregnancy was complicated by hydramnios, but labour and delivery were normal. The baby, who weighed 3870 g, had an omphalocele 4 cm in diameter. The sac contained liver and small intestines. Primary closure was performed at age 8 hours and the child had an uneventful postoperative course. There was no evidence of hypoglycaemia. He was discharged from the hospital on the 9th day. Follow-up to age 12 months shows normal development and there is no evidence of any other congenital abnormality.

Family cases. The maternal grandfather (Case 3) of Cases 1 and 2 had had an omphalocele at birth for which surgical closure had been needed. He had no other abnormality. His step brother (Case 4), who was born after his mother remarried, also had an omphalocele at birth for which surgical closure had been needed. There were no other siblings in that generation.

Discussion

Omphalocele is caused by a defect in the development of the abdominal wall. Physiological herniation of the intestines into the extra embryonic coelom of the cord occurs between the 6th and 11th week of embryonic life. Failure of the intestines to re-enter the abdominal cavity results in an omphalocele.

McKeown *et al.* (1953) reported the incidence of omphalocele as 1:3200 in Birmingham, and Soper and Green (1961) reported the incidence as 1:3800 in Ohio.

Omphalocele sometimes occurs in chromosomal aberration as part of the trisomy 13 and 18 syndromes, but its mode of inheritance as a single defect is not known.

Osuna and Lindham (1976) reported a family in which the condition was present in two generations (3 females and one male) suggesting the possibility that omphalocele could be inherited. In the present family omphalocele occurred only in male children and both male siblings of the 2nd generation were affected. All the children in the 3rd generation were female and none had omphalocele. Both male siblings in the 4th generation had omphalocele.

The distribution of the defect in this family suggests an X-linked recessive inheritance with the males being affected and the females acting as carriers.

Nonaccidental poisoning in childhood

J. B. G. WATSON, J. M. DAVIES, AND J. L. P. HUNTER

Children's Hospital, Sheffield, and Scartho Road Hospital, Grimsby

SUMMARY A boy aged 7 years 10 months was admitted to hospital on several occasions in an unconscious state with twitching and apnoeic episodes. Initial investigations failed to show a specific cause. During his time in hospital he had recurrent episodes of loss of consciousness and, on the last occasion, hypotension and ventricular tachycardia. A diagnosis of imipramine poisoning was established by the presence of imipramine in stomach washings and blood. The drug was being given to the child, both at home and in hospital, by his mother. The possibility of nonaccidental poisoning must be considered if there is no obvious cause for a child's illness. In this case the mother responded to psychiatric treatment.

The syndrome of child abuse incorporates a wide range of features including nutritional and emotional deprivation and violence. However, reports of nonaccidental poisoning are relatively rare. Meadow (1977) and Rogers *et al.* (1976) stated that occasionally parents may assault their children by administering a drug overdose. We describe the case of a child who was systematically and deliberately given toxic doses of a drug for a period of 2 months before the cause could be proved.

Case history

A boy aged 7 years 10 months was admitted to Scartho Road Hospital, Grimsby, in an unconscious state. He was twitching and had apnoeic episodes. Investigations at that time, including a full blood count, blood urea and electrolytes, and cerebrospinal fluid, were normal. He recovered consciousness over a period of 48 hours and was well on discharge from hospital 14 days later. At that time his parents, in response to specific questioning, denied that there was any possibility of the child having had an overdose of drugs. The inquiry was specific as the patient had been treated for enuresis in 1974, 1976 and, in the month before this illness, with amitriptyline. After discharge he vomited each day and was readmitted to hospital in a drowsy but rousable state one month later. He was treated with intravenous fluids for mild dehydration and his level of consciousness gradually improved. During the next week while in hospital, he had episodes of drowsiness and disorientation associated with bizarre jerking of eyes and limbs. These episodes occurred mainly in the evenings after his mother had visited him. He was referred to Dr J. Lorber at the Sheffield Children's Hospital for further assessment. At the time of transfer he was drowsy and had writhing movements of the limbs. There were no other neurological abnormalities. Again, his parents specifically denied that he had had any access to toxic drugs. He fully recovered within 12 hours of admission, and therefore no further investigations were carried out.

He was discharged but readmitted 12 days later because of gradual loss of consciousness during the previous 24 hours. He was unconscious, had myoclonic twitching of his limbs, nystagmus, hypotension,

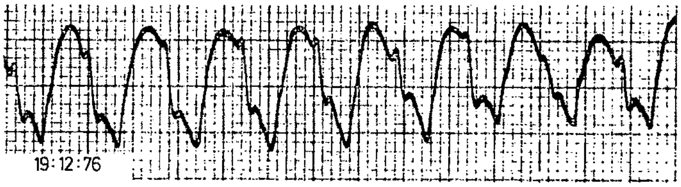

Fig. 1 *ECG before treatment.*

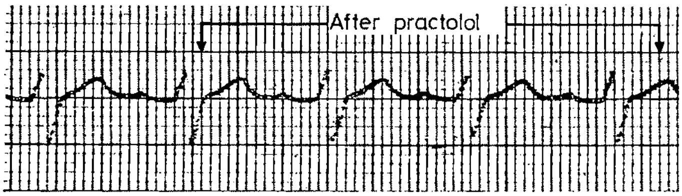

Fig. 2 *ECG after treament with practolol and lignocaine.*

and ventricular tachycardia (Fig. 1). In consultation with the general physician (D.B.C.) he was treated with synchronised DC currents 75, 100, and 200 joules without effect. The ECG reverted to normal (Fig. 2) after IV practolol and lignocaine. Treatment with IV lignocaine was continued for 24 hours. He gradually regained consciousness and was symptom-free within 3 days. Blood samples taken at the time of admission did not contain amitriptyline. 48 hours after he had become symptom-free he had further symptoms and on this occasion blood and stomach washings showed imipramine, which is the active constituent of Tofranil, to be present, together with its major metabolite desipramine, in the following amounts: stomach wash: 0·5 mg/100ml; blood: 0·15 mg/100 ml. Such a blood level could only be reached by the ingestion of several 25 mg Tofranil tablets.

On this occasion the mother admitted that she had been giving large doses of imipramine to her son, both at home and in hospital. The drug had been prescribed for her own use.

Discussion

The child's mother was found on psychiatric assessment to have a character disorder with superimposed depression. A baby girl had died suddenly just before our patient was conceived and this appeared to be the trigger factor which culminated in the administration of drugs to our patient. This projection and defence against the reality of the boy not being her 'dead daughter' was thought to lead to her giving drugs to the boy to reinforce his feminine and infantile traits and, failing this, to ensure his death just as her baby girl had died. The mother was confined to a psychiatric hospital after the incident and her depressive symptoms responded to treatment. The father was supportive throughout the period of his wife's hospital treatment. The boy returned home and after a long period of psychotherapy the mother is now also at home and under close supervision.

Nonaccidental poisoning is an unusual but potentially lethal form of child abuse. The patient may present with a variety of symptoms depending on the drug, and an awareness of the possibility of poisoning in any patient with unexplained symptoms is vital. It is not always possible, as it was in this case, to ascertain why such deliberate poisoning may occur.

We thank Dr J. Lorber for his permission to report on this patient, Dr D. B. Carron for successfully treating the child's ventricular tachycardia, Mrs P. Johnson, clinical psychologist, and the Forensic Science Laboratory at Harrogate for the estimation of amitriptyline and imipramine.

Addendum

Since this case was reported we have seen another child to whom the mother had given a drug at home and in hospital, and a solution to the problem evaded us for some time.

Quantitation of digital clubbing by shadowgram technique

D. SINNIAH AND ASMA OMAR

Department of Paediatrics, University of Malaya, Kuala Lumpur

SUMMARY Finger clubbing was quantified from the magnified silhouette of the right index finger in controls and patients with clubbing, using a simple shadowgram technique. There was good correlation between clinical assessment and measurement of both the profile angle and the hyponychial angle. The hyponychial angle appeared to be a more accurate indicator of clubbing than the profile angle.

Finger clubbing was first recognised during the time of Hippocrates as an important sign of underlying pulmonary disease (*Lancet*, 1975). Since then it has been observed in many cardiac, hepatic, and intestinal disorders as well as in some other diseases, but there have been few attempts to quantitate the degree of abnormality (Regan *et al.*, 1967; Bentley *et al.*, 1976). Clinical assessment is subjective and can be difficult in mild cases. A technique that established the presence and extent of clubbing, particularly in confusing clinical situations, and which could be used to follow its course would be valuable.

Using digital cast technique, Regan *et al.* (1967) found that the best parameter of clubbing was the hyponychial angle. Bentley *et al.* (1976) measured the magnified silhouette of the index finger and also found the hyponychial angle a better indicator than the profile angle. We report a simple method of quantifying clubbing using a shadowgram technique.

Materials and methods

A standard overhead projector (3M Company) was used to project the magnified silhouette of the distal segment of the right index finger on to a screen. The finger was positioned and supported by an assistant and the image obtained was then outlined on paper. The profile and hyponychial angles were then constructed as shown in the Figure.

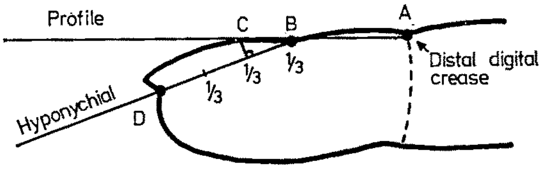

Figure *Profile and hyponychial angles.*
A = distal digital crease. B = datum point (cuticle). C = point at which a perpendicular from one-third of the distance BD meets the nail. D = hyponychium (thickened stratum corneum of epidermis lying under the free edge of nail). ABC = profile angle. ABD = hyponychial angle. (From Bentley *et al.*, 1976).

Those studied were: (a) 20 control subjects (10 boys and 10 girls) aged 1–12 years (mean 6·7 ± 3·4 SD); (b) 19 patients with clinical clubbing (obliteration of the angle of the base of the nail and abnormal fluctuation) (9 boys and 10 girls) aged 2–12 years (mean 6·9 ± 2·7 SD). The patients, comprised 10 with thalassaemia major, 5 with congenital cyanotic heart disease, 3 with malabsorption syndrome, and one with bronchiectasis. 16 of them had clubbing of all the fingers, while 3 had clubbing of the middle and/or ring finger but not of the index finger.

Results

The results are summarised in the Table. There were no significant differences between the sexes and mean ages of control subjects and patients (P>0·9; P>0·8).

Profile angle. The mean profile angle of control subjects and patients was 171·4° (SD ±5·6°, range 154–176°) and 182·9° (SD ±4·7°, range 171–189°) respectively. There were significant differences between the mean profile angles of the two groups (P<0·001).

The profile angle exceeded the normal range (171–189°) in 18 of the 19 patients and it was normal in one patient who had only slight clinical clubbing.

Hyponychial angle. The mean hyponychial angle of the right index finger of control subjects and patients

Table *Profile and hyponychial angles of the right index finger of control subjects and patients with clinical clubbing*

	Controls (*n* = *20*)	*Patients* (*n* = *19*)	*t value*	*P*
Age (years)				
Mean ± SD	6·7±3·4	6·9±2·7		
Range	1–12	2–12	0·2	0·9>P>0·8
Profile angle °				
Mean ± SD	171·4±5·5	182·9±4·7		
Range	154–176	171–189	7·0	<0·001
Hyponychial angle °				
Mean ± SD	180·7±5·2	194·5±7·5		
Range	165–189	178–205	6·7	<0·001

was 180·7° (SD ±5·2°, range 165–189°) and 194·5° (SD ±7·5°, range 178–205°) respectively. There were highly significant differences between the mean hyponychial angles of the two groups ($P < 0 \cdot 001$).

16 of the 19 patients had profile angles which exceeded the normal range, while 3 with clinical clubbing of the middle and/or ring finger, but not of the index finger, had normal angles. There was good correlation between the clinical diagnosis of clubbing and assessment by the shadowgram.

Discussion

Clinical assessment of finger clubbing is subjective and unreliable (Pyke, 1954; Carroll, 1972) but it is very useful as an indicator of underlying disease. The shadowgraph is a cheap and simple technique which allows serial measurements of the profile and hyponychial angles to be made speedily and without discomfort. There is excellent correlation between the clinical diagnosis of clubbing and assessment by this technique. The hyponychial angle appears to correlate more closely with the clinical diagnosis than the profile angle, as was found by Regan *et al.* (1967) and Bentley *et al.* (1976).

Fatal bleeding from gastric ulceration during first day of life—possible association with social stress

R. J. PUGH, R. W. NEWTON, AND D. M. PIERCY

Departments of Paediatrics and Pathology, Hull Royal Infirmary, North Humberside

SUMMARY Death from haemorrhage is described in a 21-hour-old baby boy with acute gastric ulceration. Particular note is made of the very high level of psychosocial maternal stress during the last trimester of pregnancy. A causal relationship of this stress and the peptic ulceration is suggested, with gastrin as the mediator.

A 17-year-old primigravida was admitted in labour after an uncomplicated pregnancy and monitored cardio-tocographically without causing concern. The first stage of labour lasted 5 hours and the second 20 minutes, producing a healthy baby boy at term, weighing 2·73 kg, by a spontaneous normal vaginal delivery. The Apgar score was 4 at one minute and 8 at five minutes. No special resuscitative procedures were needed, no nasogastric tube was passed, and vitamin K 1 mg was administered intramuscularly.

The baby had normal infant care alongside its mother, taking 5% dextrose solution eagerly by bottle until, at age 20 hours, fresh blood was vomited and shown by Apt's test to be of infant origin. Clinical examination then showed a vigorous baby with no purpura, bruising, or haemangiomata. There was no family history of bleeding disorder, and no aspirin or similar drugs had been administered to the mother at the relevant time. The mother was in good health. A venous blood sample on admission at 20 hours showed the baby to have a haemoglobin of 14·2 g/dl, a platelet count of $160 \times 10^9/l$ (160 000/mm^3), and no abnormality in the prothrombin, partial thromboplastin, or thrombin times. A similar coagulation screen of the mother's blood was also normal.

During the next half-hour further fresh blood was vomited repeatedly, resulting in a critical degree of shock with apathy and loss of awareness. A catheter introduced into the inferior vena cava via the umbilical vein recorded a low central venous pressure and 75 ml of O-negative whole blood was transfused rapidly with only fleeting benefit. Death supervened at 21 hours, only one hour after the first haematemesis.

Necropsy showed the source of bleeding to be 3 areas of gastric ulceration: 2 on the posterior wall and one on the greater curvature (Figure). Histological examination showed that they were of the acute peptic

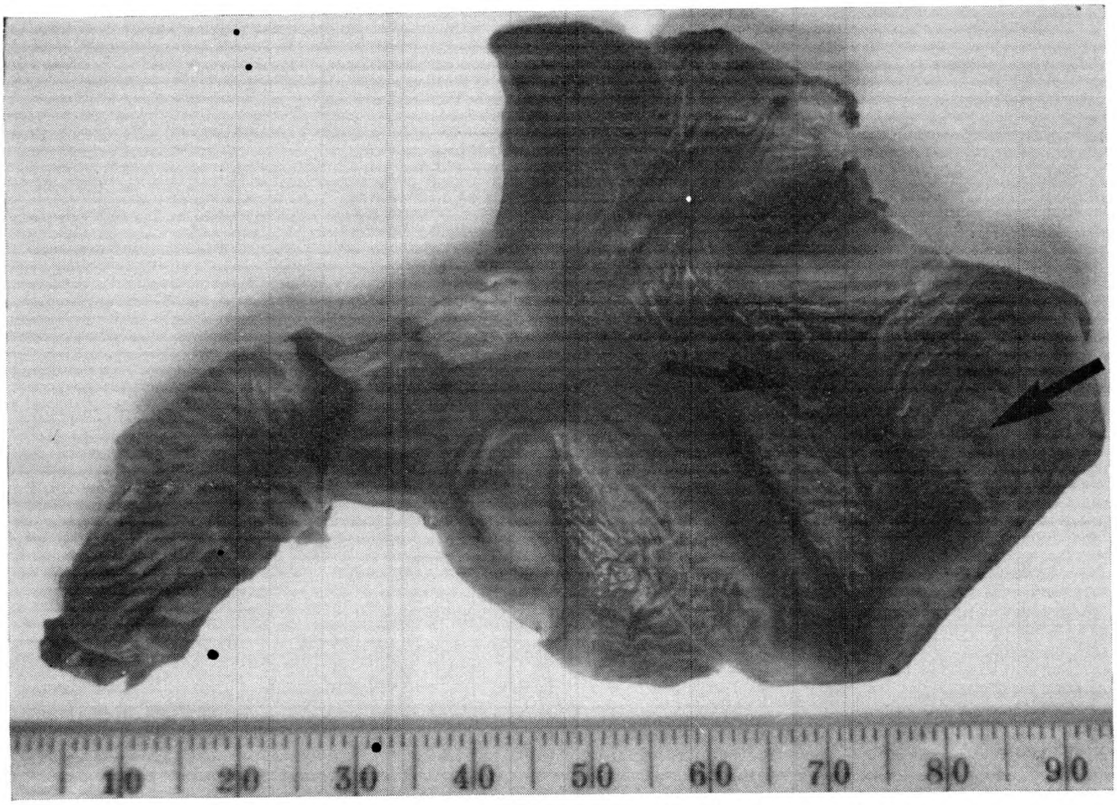

Figure *Two peptic ulcers on the posterior gastric wall (note remnant blood clot in upper ulcer).*

type with endarteritic changes in the smaller, most distal, ulcer.

After this tragic death a discreet social inquiry found that the pregnancy, and particularly the last trimester, had been exceptionally stressful and unhappy. At the time of conception the mother was only 16, unmarried, and working in a factory as a hosiery examiner. She married the equally young father to comply with parental wishes, but lived with him for only 2 weeks before returning to her parents' home to escape from drunken physical assaults. Subsequently her husband made frequent visits to her parents' home in ill-conceived attempts at reconciliation, causing great distress, panic, and revulsion. One such visit shortly before labour began culminated in a brick being thrown at her through the living-room window and the intervention of the police.

Comment

The occurrence of peptic ulceration in the newborn infant, particularly in boys, has often been described. Presentation is usually with haematemesis or perforation (Bird *et al.*, 1941; Smith, 1975). We know that stress increases the incidence of peptic ulceration in adults (Rose, 1978) and the possibility exists that greatly increased maternal stress late in the pregnancy may have a similar association with gastric ulceration in the newly born—presumably mediated by a maternal hormone crossing the placenta.

When gastrin is administered to the experimental dog late in pregnancy there is an increased incidence of pyloric stenosis, in some cases associated with pyloro-duodenal ulceration in the offspring (Dodge, 1970; Karim *et al.*, 1974). Dodge (1972) and Revill and Dodge (1978) drew attention to the higher incidence of maternal stress in the latter part of pregnancy in babies with pyloric stenosis and suggested that gastrin is the biochemical mediator.

We believe our patient to be the first in whom gastric ulceration with bleeding in the first day of life has been tentatively identified with maternal stress as cause and effect. It is possible that in this case gastrin was the biochemical mediator of the stress and the cause of gastric ulceration.

Conclusion

A careful social history may be particularly relevant in high gastrointestinal bleeding or perforation in the early newborn period. Conversely, such pregnancies should be regarded as particularly at risk and managed accordingly.

Hepatomegaly due to self-induced hyperinsulinism

JACK ASHEROV, MARC MIMOUNI, ITZHAK VARSANO, ERNESTO LUBIN, AND ZVI LARON

Institute of Paediatric and Adolescent Endocrinology, and Department of Nuclear Medicine, Beilinson Medical Centre, Petah Tikva, and the Sackler School of Medicine, Tel Aviv University, Israel

SUMMARY Repeated hypoglycaemic attacks, associated with transient hepatomegaly, in a 12-year-old insulin-dependent diabetic girl continued despite reduction in dose and, later, complete discontinuance of insulin. The attacks ceased while she was in hospital, necessitating reinstitution of insulin. The hepatomegaly resolved when surreptitious additional insulin injections were discovered and stopped. Hepatomegaly in diabetics should arouse suspicion of over dosage with insulin.

Hepatomegaly associated with diabetic hypoglycaemia was well known before long-acting insulin became available (Madison, 1969), but it has seldom been encountered recently (Rosenbloom and Giordano, 1977). We present a 12-year-old insulin-dependent diabetic with transient hepatomegaly associated with hypoglycaemia induced by surreptitious additional insulin injections, and discuss the role of over dosage with insulin in inducing hepatomegaly.

Case report

We have followed-up a 12-year-old girl since age 5 when insulin-dependent diabetes was diagnosed and treatment initiated. For 7 years control was good, but then frequent hypoglycaemic attacks of moderate severity were reported. The hypoglycaemic attacks persisted despite reduction in insulin dose and, later, its complete discontinuance. Marked hepatomegaly was noted, and the girl was admitted for investigation.

She was then a lean, normotensive, healthy looking child with a firm, tender liver palpable 12 cm below the costal margin. SGOT 138 IU/ml (normal <40), LDH 156 IU/ml (normal <235), alkaline phosphatase 181 IU/ml (normal for age), acid phosphatase 1·5 U/ml (normal 0–1), bromosulphalein retention 2·4% after 45 min, serum ammonia 57 μg/100 ml (normal <85), antitrypsin 88 mg/100 ml (0·88 g/l) α-fetoprotein negative; normal bilirubin, electrolytes, and copper ceruloplasmin. Australian antigen tests, endocrinological studies including evaluation of pituitary and adrenal, and haematological study, including bone marrow aspiration, were all normal. Scan showed diffuse liver enlargement and a normal spleen (Fig. 1a).

After 3 days without treatment, the fasting serum insulin was 5·2 μU/ml. Because of hyperglycaemia (up to 405 mg/dl) and glycosuria (up to 4%), the insulin was restarted. The hypoglycaemic attacks then ceased, the liver size decreased to 6 cm below the costal margin, and she was discharged.

After 5 months of good control in which only the edge of the liver remained palpable (Fig. 1b) the hypoglycaemia and hepatomegaly recurred. Because of the history and laboratory findings, we suspected overinsulinism. The mother then discovered that the girl surreptitiously injected additional insulin, probably to attract notice by provoking hypoglycaemic spells.

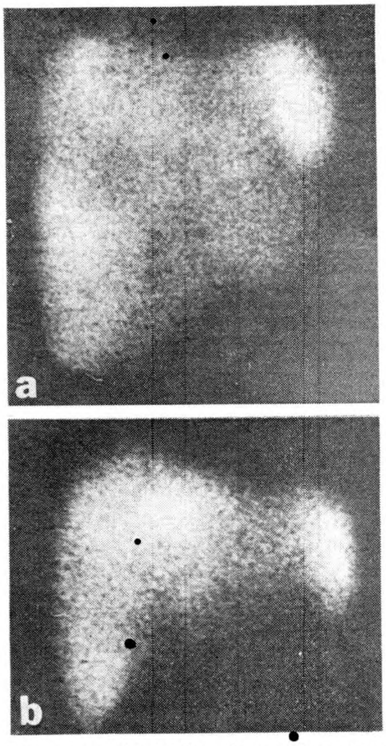

Figure *Liver scan.* (*a*) *Diffuse liver enlargement during overinsulinism;* (*b*) *Decreased liver size after adjustment of insulin dose.*

We insisted that the extra insulin injections be stopped and referred the girl to a psychologist. The hypoglycaemic episodes then disappeared and the hepatomegaly resolved within a few weeks.

Discussion

After excluding diseases associated with hepatomegaly, the diagnosis lay between uncontrolled diabetes and over dosage with insulin. The long periods of good control and disappearance of hypoglycaemia during observation in hospital favoured the latter.

Rosenbloom and Giordano (1977) reviewing overtreatment in diabetic children noted findings similar to those of our patient. Hepatomegaly associated with protracted hypoglycaemia was noted before the availability of long-acting insulin, mainly among poorly controlled juvenile diabetics treated with daily, multiple injections of regular insulin (Mandell and Berenberg, 1974). The hepatomegaly of hyperinsulinism is thought to be secondary to accumulation of glycogen in the liver by inhibition of cyclic-AMP synthesis (Bishop *et al.*, 1965; Mortimore *et al.*, 1967; Davidson and Berliner, 1974; Dershewitz *et al.*, 1976). Insulin is known to affect hepatic glucose metabolism directly (Madison, 1969) by increasing the uptake and decreasing the output (Steele *et al.*, 1965). Liver glucose output is largely determined by opposing effects of insulin and glucagon (Jefferson *et al.*, 1968). Glucagon increases the hepatic cyclic-AMP, thus stimulating glycogenolysis and gluconeogenesis (Robison *et al.*, 1971). Insulin opposes this effect by inhibiting the synthesis and increasing the degradation of cyclic-AMP (Jefferson *et al.*, 1968), thus leading to increased glycogen storage.

The excessive insulin taken by our patient undoubtedly disturbed the balance between insulin and glucagon, leading to increased glycogen storage in the liver which presumably was responsible for the hepatomegaly. Stopping the insulin overdose, enabled the glucagon to increase the synthesis of cyclic-AMP, thus inducing gycogenolysis and resolution of the hepatomegaly.

Phenothiazine-induced dystonia associated with an increase in serum creatine phosphokinase

W. Y. LUI

Department of Paediatrics, University of Hong Kong

SUMMARY A transient but considerable rise in serum creatine phosphokinase (CPK) levels occurred in six boys aged between 8 and 11 years and suffering from phenothiazine-induced dystonia. In one boy (Case 4), after the CPK level had returned to normal after withdrawal of the drug, its reintroduction orally at lower dosage caused a slight increase in the level of CPK in the absence of any recurrence of the dystonia.

Muscle dystonia associated with administration of certain phenothiazine derivatives is well known (Goldsmith, 1959; Ayd, 1961). Laboratory investigations in such patients have been normal. In a survey of serum creatine phosphokinase (CPK) levels in Chinese children, it was noticed that there was a transient increase in CPK levels in some children who suffered drug-induced dystonia.

Material and methods

Six Chinese boys aged between 8 and 11 years were admitted for dystonia into this hospital. Four had received phenothiazine derivatives orally. A single IM injection of prochlorperazine had been given in 2 other boys. None had a disease known to be associated with raised levels of CPK. Apart from the 2 boys who each had received one IM injection of prochlorperazine, none had had any medical treatment known to cause an increase in CPK. Their clinical details are given in the Table. Between 24 and 48 hours after oral or IM administration of the drug, the child generally developed painful spasms of facial, neck, and sometimes limb muscles. The head and sometimes the eyes were deviated involuntarily to one direction. The mouth was open, or spasmodic attacks of trismus occurred. One or more extremities, and at times the whole body, might be held spasmodically in a bizarre posture. The child was invariably conscious but could not speak as a result of muscle spasms.

IV diphenhydramine was given to 4 boys after being in hospital; the other 2 received no treatment. Dystonia subsided within 36 hours in all 6 boys, but pain in affected muscles persisted for 2 to 7 days.

Serum was collected immediately after admission and then serially. CPK was assayed immediately after collection or after storage in dark containers at −20°C for not more than 5 days. A colorimetric method using Sigma kit 661-PB was used. The normal range with this method in Chinese boys of this age group is 2–17 Sigma units/ml.

Table *Clinical details and serum CPK levels*

Age (years)	*Drug responsible*	*Dystonia*		*Features*	*Duration of muscle pain (days)*	*Peak serum CPK level* (Sigma units/ml)*	*Duration of raised serum CPK*
		Onset (hours)	*Duration (hours)*				
9½	Prochlorperazine 5 mg oral × 2 for vomiting	Within 24	24	Torsion head and neck	4	104	Days 2–6
11	Perphenazine 2 mg oral × 3 for vomiting	Within 24	36	Torsion head and neck	2	84	Days 2–5
9	Haloperidol 0·5 mg oral for behavioural problems	Within 24	48	Torsion head, oculogyric crisis, mouth open, salivation, sweating	3	30	Days 2–4
8	Haloperidol 1 mg oral × 3 for behavioural problems	Within 36	24	Trismus, torsion head and neck	7	74	Days 2–6 11 (see text)
9½	Prochlorperazine 12·5 mg IM for vomiting	Within 24	24	Torsion head and neck, rigid limbs	2	135	Days 2–3
11	Prochlorperazine 12·5 mg IM for vomiting	Within 24	24	Oculogyric crisis torsion head and neck	2	97	Days 1–3

*Normal range 2–17 Sigma units/ml.

Results

In all 6 boys, serum CPK was abnormally high, reaching a peak level between 2 and 4 days after the onset of dystonia. Thereafter the levels dropped to normal within a week. The peak levels reached ranged from 30 to 135 Sigma units/ml.

In one 8-year-old boy (Case 4), in whom dystonia had been induced by three oral 1 mg doses of haloperidol given within a day (for psychiatric symptoms), the peak CPK level was 74 Sigma units/ml. After withdrawal of haloperidol, the level fell to 9 Sigma units/ml in a week. Three days after reintroducing the drug at 0·5 mg twice a day, his CPK level rose to 19 Sigma units/ml, but without any recurrence either of muscle pain or dystonia.

Discussion

Raised levels of serum CPK have been known to be associated with active progressive muscular dystrophy, acute polymyositis, periodic paralysis, repeated intramuscular infections, strenuous exercise, myocardial infarction, and cardiac catheterisation, and also with the immediate newborn period. Although increased levels of CPK have been reported in patients with Wilson's disease who had marked rigidity (Okinaka *et al.*, 1964), its increase in patients suffering from drug-induced dystonia was not reported. With severe muscle dystonia, this enzyme may perhaps be released into the circulation. Previous reports on phenothiazine-induced dystonia found no correlation between the dosage or route of administration of the drug, and the occurrence and severity of dystonia (Goldsmith, 1959). It is notable however that in our Case 4 the CPK level rose again on reintroducing the drug at a lower dosage but did not cause dystonia or muscle pain. This raises the possibility that the offending drug at a lower dosage may lead to subclinical disturbances of muscle function.

Paediatric Pathology Society

Proceedings of the Twenty-fourth Annual Meeting

The meeting was held on 21–23 September 1978 at the Bristol Maternity Hospital. Lack of space precludes the publication of summaries of all the unusually large number of papers read.*

Morbid anatomists' role in a diagnostic amniocentesis service. D. I. Rushton. Department of Pathology, Birmingham Maternity Hospital, Birmingham.

The role of the morbid anatomist in a diagnostic amniocentesis service is primarily (a) to assess the wastage due to the procedure and (b) to confirm antenatal diagnoses resulting from examination of amniotic fluids. The description of the fetal manifestations of disease is also important. The inadequacies of current services and the dangers of failure of consideration of normal patterns of pregnancy wastage at the appropriate gestation are stressed. It is suggested that data may give a falsely low estimate of fetal wastage attributed to amniocentesis.

Pathology of congenital disclocation of the hip. P. M. Dunn. Department of Child Health, Southmead Hospital, Bristol.

During the period 1961–75 50 hips considered on clinical examination to be either dislocatable or dislocated at birth were examined at necropsy. All the infants died during the neonatal period, most of them within 3 days of birth. Gestational ages ranged from 27 to 44 weeks. 16 of 33 infants had presented by the breech at delivery. Infants with obvious or suspected neuromuscular disease were not included. Dissection confirmed abnormality in each case. Pathology ranged from instability of the fibrocartilaginous labrum with increased joint laxity in the dislocatable hips to full dislocation with inturned limbus compressed between the outlying head of femur and true acetabulum. One hip was dysplastic without being dislocated. No case of 'fixed', stable dislocation was encountered. The degree of abnormality often varied between the two hips, and every combination from normality to mild or severe change was found. At least 50 hips considered normal on clinical examination were dissected and normality was confirmed. These findings, and the results of epidemiological studies, suggest that congenital dislocation of the hip may be defined as a deformity of the hip joint, arising during fetal life and present at birth, in which the head of the femur is, or may be, partially or completely dislocated from the acetabulum. The findings also show that hip disease is common at birth and may reliably be detected by clinical examination.

Tyrosinaemia—an atypical case. J. T. Ireland and C. Davidson. Alder Hey Children's Hospital, Liverpool.

Toxicological screening in cases of sudden infant death syndrome. C. N. Chapman and N. J. Brown. Bristol Maternity Hospital, Bristol.

Using an analytical scheme designed to detect drugs most likely to be encountered, a screening programme was initiated. It was thought this might show the presence of substances which, if not the prime cause of death, might have contributed thereto. Samples of stomach contents and liver were examined from 47 cases, with the following results: no drugs detected —31; benzodiazepines—5; phenobarbitone—3; unidentified acid compound—1; unidentified basic compound—7. The unidentified compounds are not necessarily drugs; they could well be post-mortem decomposition products. The amounts of material detected were very small. There was no case of anything that might be called an overt example of poisoning.

Fetal pathology: termination of pregnancy in the second trimester. A. A. M. Gibson. Royal Hospital for Sick Children, Glasgow.

A series of over 150 cases in which the indication for termination of pregnancy was the antenatal diagnosis of fetal malformation.

Differential delay in myelination of vagal fibres—its relation to apnoea of prematurity and the sudden-infant-death syndrome. P. N. Sachis, D. L. Armstrong,

---

*Abstracts may be obtained from Dr R. A. Risdon, Secretary, Paediatric Pathology Society, Institute of Pathology, The London Hospital, London E1 1BB.

L. E. Becker, and A. C. Bryan. Departments of Pathology and Respiratory Physiology, The Hospital for Sick Children, Toronto, Canada.

Apnoea is especially common in premature infants, and abnormal control of breathing has been implicated in the sudden-infant-death syndrome (SIDS). Because vagal pulmonary reflexes change with maturation, we studied 'normal' morphological vagal ontogeny and compared this with the morphology in SIDS victims. Total and small myelinated fibres (MF) were sparse in premature infants. In vagi of 'SIDS-age' infants, despite the lower mean postconceptional age, their mean MF total compared with that in SIDS: however, small MF were significantly fewer in SIDS—only slightly more than in the premature. Lack of myelin impairs temporal summation of excitatory postsynaptic potentials and may alter the nature of both afferent and efferent signals. As 1–2 μm is the critical diameter where myelination increases conduction velocity, our findings accord with the reduced neural respiratory control in premature infants and may relate to SIDS.

Histochemical and densitometric study of cartilage in a case of achondrogenesis type II. J. J. van der Harten, G. J. M. Hooghwinkel, and D. Toornvleit. Free University, Amsterdam, The Netherlands.

Asplenia-polysplenia: a comparative study of susceptibility to infection. V. Mahnovski, V. M. Anderson, and A. I. Lipsey. Department of Pathology, Children's Hospital of Los Angeles, California, USA.

Asplenia in the Ivemark syndrome—evidence against primary agenesis. V. M. Anderson and V. Mahnovski. Department of Pathology, Children's Hospital of Los Angeles, California, USA.

Pulmonary and myocardial changes in premature infants after mechanical ventilation. H. Nordgren and A. Petersson. Department of Pathology, University Hospital, Lund, Sweden.

19 premature infants, gestational ages 26–40 weeks, treated with mechanical ventilation were studied at necropsy. A comparison was made between gestational age, weight, time of ventilation, age at death, and microscopical changes in lungs and myocardium. The lung changes were classified according to the criteria suggested by Rosean and the myocardial changes were graded into three groups ranging from oedema to calcification. Three different groups were easily distinguishable. The 1st, ventilated for 1–7 days, showed only minor changes in myocardium and lungs. The 2nd, ventilated for 9–14 days, showed more obvious changes—BPD II–III and slight myocardial fibrosis. The 3rd group, ventilated for 1–6 months, showed severe, apparently irreversible damage—BPD III–IV, and fibrotic scarring of the myocardium; in some cases calcification was observed. The myocardial changes were particularly prominent in the subendocardial zone in the right ventricle. These changes indicate ischaemic damage, and the presence of calcification supports the theory that ischaemic damage leads to an increase of the cellular calcium concentration.

Betamimetics and neonatal lung adaptation. B. Bergman, U. Freyschuss, G. Grossman, T. Hedner, B. Lachmann, and B. Robertson. Department of Paediatric Pathology, Karolinska Institutet, Stockholm, Sweden.

There is now evidence that certain betamimetic agents, administered to the mother or injected into the premature fetus, have a direct influence on the developing lung by stimulating a release of surface active phospholipids in the fetal pulmonary fluid (FPF) and by reducing the water content of the fetal lung. To analyse whether antenatal treatment with a betamimetic agent influences neonatal lung mechanics *in vivo*, we recorded pneumotachogram and oesophagus pressure in premature rabbit neonates, delivered on day 28 of gestation, 3 hours after IM injection of terbutaline (0·1 mg). In recordings made 30 min after birth, we found reduced expiratory resistance in treated animals, but otherwise no difference between experimental neonates and controls. Thus, although administration of beta-stimulants to the premature fetus has a strong influence on the amount and composition of FPF, and although the pressure/volume characteristics of the neonatal lung appear to be improved after such treatment, these effects seem to have only slight influence on lung mechanics during the subsequent phase of neonatal adaptation.

A breakdown of factors present with children found unexpectedly dead. J. L. Emery and P. M. McWeeny. Children's Hospital, Sheffield.

A survey was carried out of the morbid anatomical findings and the clinical history, based largely on a home visit by a social research worker, from a sequential series of about 100 postperinatal deaths in the Sheffield area before March 1976. In most cases there were multiple factors. Necropsy showed that over one-third of the babies had evidence of what was probably subclinical damage to the brain dating from the perinatal period. Many terminal diseases were present, only a few of which would usually be considered adequate causes of death in themselves. There were a few deaths that were probably not due to natural causes but were, at presentation, legally unprovable and indistinguishable from unexplained deaths. Social factors show many features affecting the child that were acting before the child's birth and a variety of defects in the interfaces between the family and the health service, and within the health service itself. The findings give a hint of the features that could well be shown to be variable throughout the country when the findings of the current multicentre study will be completed.

Thymus reaction and its relationship to duration and severity of symptoms in infants. J. W. Keeling, D. Scott, I. Forrest-Hay, and J. Oakley. DHSS Multicentre Post Perinatal Mortality Study.

Hydrops fetalis and diffuse arterial calcification. J. W. Keeling and J. D. Baum. John Radcliffe Maternity Hospital, Oxford.

Critical study of thymic pathology in children with malnutrition infection morbid complex. K. Madi, C. L. Ávila, and A. V. Oliveira. Departamento de Patologia, Universidade Federal do Rio de Janeiro, Brazil.

Malnutrition has been held responsible for a type of thymic hypoplasia common in children from underdeveloped countries. Evidence shows that this hypoplasia is caused by a combination of malnutrition, infection, and stress. Two types of lesion are described: *thymic involution*, where, besides reduction of size and of lymphoid population (which produces blurring of cortico-medullary demarcation) there is cystic dilatation of Hassall's corpuscles; and *atrophy*, where, besides severe weight loss, Hassall's corpuscles are absent or reduced in number and size. There is similar lymphoid hypoplasia in the other organs with rudimentary follicles in the lymph nodes and spleen, and hypocellularity of intestinal lamina propria. The number of cases with absence of Hassall's corpuscles is large enough to discourage the authors from considering them as a primary immunological deficiency. In addition it is argued whether some thymic hypoplasias described as congenital are really the result of a process similar to that seen in our cases.

Vascular changes in the lungs of infants following parenteral lipid nutrition. A. Moragas and A. Ballabriga. Departments of Pathology and Paediatrics, Ciudad Sanitaria de la Seguridad Social and Facultad de Medicina Automoma de Barcelona.

In a necropsy series of 22 infants aged 7–123 days who had received parenteral lipid nutrition from 4 to 27 days, lipid droplets in alveolar capillaries were found in 8 cases (36%), lipoid alveolitis in 3 (14%), and severe changes associated with fat deposition in intrapulmonary arteries from 0·1–0·6 mm diameter in 17 (77%). According to the prevalent type of arterial lesion the cases were classified in stages I to IV (early lesions, acute florid stage, lipophagic stage, and regressive stage) which showed a good correlation with the length of lipid treatment or the lapse of time between the start of treatment and death. All the early cases and 88% of florid acute cases were found in infants treated for up to 8 days. It is suggested that the lesions develop differently in term compared with premature babies, the latter showing a prevalence of acute florid lesions with little lipophagic response. The main factor in the pathogenesis of the lesions is considered to be previous injury to the arterial wall mediated by hypoxia or acidosis. It is assumed that the degree of lipidisation does not depend primarily on the length of lipid treatment, since there is a tendency for this to regress with time. It is not known if a persistent narrowing of pulmonary vessels could be a significant cause of pulmonary hypertension in later life.

Tentorial tears as a problem for the paediatrician. A. J. Barson. Department of Pathology, St Mary's Hospital, Manchester.

40 infants dying from intracranial haemorrhage secondary to tentorial tears between 1967 and 1978 were reviewed. Increased numbers of such deaths have been seen since the establishment of a regional service for the intensive care of the newborn infant. This is because priority for admission has tended to be given to infants with respiratory difficulty which cannot easily be accounted for either by prematurity or gross malformation. Although most of these infants die within 48 hours of birth it is difficult to differentiate them from infants with uncomplicated respiratory distress syndrome in whom the prognosis is much better. Indeed one-quarter of the infants with tentorial tears also had hyaline membrane disease at death, and about one-third had some form of internal congenital malformation. The incidence of tentorial tear is approximately 1 per 1000 births and does not seem to have changed significantly during the last decade. However, the development of intensive care facilities for the newborn with respiratory difficulty has made this a major problem for the neonatologist.

Congenital cystic disease of lung. P. M. Bale. Royal Alexandra Hospital for Children, Sydney, Australia.

44 cases of cystic lungs in children were studied in an attempt to determine (1) how often congenital cystic disease could be clearly distinguished from post-inflammatory pneumatoceles and bronchiectasis, and (2) whether true congenital cystic malformation and adenomatoid malformation were separate entities or variants of the same condition. 22 cases were classed as congenital cystic malformation, 2 as adenomatoid malformation, and one as intrapulmonary bronchogenic cyst. In 16 cases chronic inflammation and fibrosis precluded differentiation of inflammed congenital cystic disease from post-inflammatory pneumatocele, and 3 were intermediate between lobar emphysema and cystic malformation. Cystic and adenomatoid malformations were considered to be similar bronchiolar malformations falling into 2 overlapping clinico-pathological groups: (1) cystic malformation in term infants and children with predominantly cystic lobes and interspersed mature alveoli, and (2) adenomatoid malformation in oedematous stillborn and premature infants with predominantly solid lobes showing more epithelial proliferation and immature terminal airways.

Pancreatic changes in the normal and cystic fibrosis infant. J. R. Imrie, D. G. Fagan, and J. M. Sturgess. The Hospital for Sick Children, Toronto, Canada.

The clinical and pathological diagnosis of cystic fibrosis (CF) in infants, with or without meconium ileus, often proves difficult, and is subjective. To establish objective criteria of the morphological changes, the exocrine pancreas of CF and normal children was analysed by quantitative stereological techniques. In the normal pancreas, the ratio of acinar to connective tissue increases linearly from 32 to 54 weeks' postconceptional age (PCA). In CF, there is a reversed pattern of development: the ratio of acinar to connective tissue decreases linearly and the values are significantly different from the controls after 42 weeks' PCA. Thus lack of acinar developmend and/or degeneration appears similar in all CF patients, with or without a history of meconium ileus. Dilatation of pancreatic ducts and acinar lumina with inspissated secretions results in an increased lumen volume in 83% of CF infants. This change is independent of the acinar and connective tissue variation and indicates that obstruction of ducts is not the only factor responsible for acinar maldevelopment, degeneration, and fibrosis. After analysis of both the acinar to connective tissue ratio and lumen volume, only 2 out of 30 CF infants defied differentiation from normal controls. By quantitative microscopy, we developed the basis for a simple objective diagnostic method for CF by examining the pancreas alone. This may prove valuable in confirming a tentative diagnosis of CF in the absence of clinical proof, and so aid genetic counselling.

Thymus pathology and lymphadenopathy in children. B. Woźniewicz. Department of Paediatric Pathology, Medical School of Warsaw, Poland.

Precocious thymic atrophy was found in about half of 3000 consecutive necropsies. Advanced thymic atrophy (producing so-called thymic remnants or rudiments) was seen in 6% of cases including 3 of thymus dysplasia and 3 of athymia. In each case the peripheral lymphatic system was examined microscopically and, in some, by EM and cytochemistry. Severe thymic atrophy was associated with lymphadenopathy. It consists of T-zone atrophy, lymphocyte depletion, the appearance of lymphoblasts, immunoblasts, histiocytes, and Strernberg-like cells, incrustation of reticular fibres with PAS-positive deposits, and accentuation of the vascular pattern. It is suggested that thymic atrophy and immunological lymphadenopathy may precede malignancy. It was also shown that malignant lymphomas, leukaemias, and malignant histiocytic proliferations in children were associated with thymic atrophy in about 70% of cases.

Pulmonary sequelae of epidemic type-21 adenovirus infection: a 13-year follow-up. D. M. O. Becroft. The Princess Mary Hospital for Children, Auckland, New Zealand.

43 infants aged 3–18 months were admitted to hospital in 1965 with acute lower respiratory tract infections which ran a prolonged course. Type-21 adenoviris was isolated from 21 children and the outcome in 18 of these was reassessed in 1978.Three had died of respiratory disease. 15 were examined clinically and radiologically, and 11 had lung function tests. 11 had abnormal chest *x*-rays and, of these, 9 had bronchiectasis. Two of the 4 with normal chest *x*-rays had abnormal lung function tests. Bronchiolar obliteration was the most consistent pathological finding in the lungs of 5 cases and is the expected sequel of the bronchiolar mucosal necrosis of acute adenoviral infection. Bronchiectasis was found 4 months after the acute infection in one infant. Three persistently collapsed lungs, removed 1, 3, and 5 years after the acute infections, showed the secondary inflammatory changes in bronchi typical

of the follicular type of bronchiesctasis. Another lobectomy specimen obtained 12 years after the acute infection in an asymptomatic child had thin-walled dilated bronchi with little inflammation, i.e. a cystic or saccular bronchiectasis. The extent of early bronchiolar obliteration apparently determines the severity of chronic postadenoviral pneumopathy and the development of bronchiectasis.

Histology and ultrastructure of the prepubertal and pubertal testis following combination chemotherapy. M. Lendon and H. B. Marsden. Department of Pathology, University of Manchester, and Royal Manchester Children's Hospital.

The assessment of gonadal function has become increasingly important in children with acute lymphoblastic leukaemia as longer survival is achieved by the use of cytotoxic treatment. The deleterious effects of drugs—such as cyclophosphamide and chlorambucil—on men are well known. Reports on the testicular histology after this treatment in children are few and contradictory. Since mid-1977 we have studied bilateral testicular biopsies from 44 boys (27 prepubertal and 17 pubertal) with acute lymphoblastic leukaemia. All the boys had received a variety of therapeutic regimens. Each biopsy was assessed by light microscopical examination for the following histological parameters: leukaemic infiltration, interstitial fibrosis, basement membrane thickening, the presence or absence of Leydig cells, and the presence or absence of spermatogenesis. Two morphometric studies were performed—the mean tubular diameter and the tubular fertility index, and each biopsy was examined by electron microscopy.

Identification of Niemann-Pick disease. A. D. Bain and G. T. N. Besley. Department of Pathology, Royal Hospital for Sick Children, Edinburgh.

Review of congenital heart disease in Poland studied pathologically. K. Karczeński. Department of Pathomorphology, Institute of Paediatrics of the Medical School, Warsaw, Poland.

Congenital heart disease in Poland now occupies 4th place among the principal causes of death under 12 months of age and accounts for approximately 40% of all fatal congenital malformations. The number of cases of congenital heart disease in Poland for the last few years is still rising—in absolute and relative terms. The Institute of Paediatrics in Warsaw is the main centre in Poland for children with congenital heart disease. Congenital cardiovascular malformations have been encountered in 1276 cases out of 3792 consecutive necropsies performed on children. All the data presented are complete and unselected. The most common were: transposition complex—286 cases; septal defects—248 cases; Fallot's syndrome—220 cases. The different congenital cardiac complexes have been analysed and correlated with the sex and age distributions. The incidence of extracardiac birth defects accompanying cardiac defects was also analysed.

Gonadal infiltration in childhood leukaemia and lymphoma—a post-mortem survey. H. Reid and H. B. Marsden. Department of Pathology, University of Manchester, and Royal Manchester Children's Hospital, Manchester.

In children with leukaemia, extramedullary sites, in particular the CNS and more recently the testis, have been incriminated as causes of relapse. In view of the current interest in testicular disease in acute lymphoblastic leukaemia, a survey was undertaken to determine the exact incidence of gonadal infiltration from the necropsy files of the Royal Manchester Children's Hospital. There were 96 cases of leukaemia and lymphoma—65 boys and 31 girls. Sections of testes were examined for the presence and degree of infiltration, interstitial fibrosis, and assessment of numbers of spermatogonia. Sections of ovaries were examined for the presence and degree of infiltration by leukaemia and lymphoma.

Congenital cardiac malformation and ischaemic cerebral lesions. F. Ochsner, J. N. Cox, and B. Friedli. Institut Universitaire de Pathologie, Geneva, Switzerland.

An anatomical and statistical analysis of ischaemic cerebral lesions in association with various types of cardiac abnormalities are reported. There were 227 cases with ages ranging from birth to 20 years. The cerebral lesions encountered were grouped into five categories: (1) infarction (with or without thrombolism); (2) diffuse lamina; (3) focal lesions on the watershed areas; (4) venous thrombosis; and (5) lesions affecting the white matter and central nuclei. 27% of cerebral lesions were observed in this series. An attempt was made to correlate the various types of cerebral lesions with the types of cardiac malformations, taking into account those which were catheterised and/or operated upon. 20% of the cases presented cerebral anomalies and in 4% there were infectious complications; these were not included in the study.

A morphological classification of enterocolitis in infancy. K. Madi, C. M. Ávila, E. T. D. Ávila, D. de Paola. Departamento de Patologia, Universidade Federal do Rio de Janeiro, Brazil.

In a review of 1400 necropsies, 380 cases of intestinal inflammatory lesions were selected and classified on a morphological basis. Most cases were in infants between 2 and 6 months of age. Malnutrition was common. The lesions were classified as follows: (1) *Enterocolitis* (*EC*) *with predominance of acute changes*: (a) catarrhal EC; (b) typhoid-like EC; (c) necro-haemorrhagic EC (diffuse or patchy necrosis, small bowel predominance); (d) papulo-necrotic EC (focal, nodular, or follicular necrosis, large bowel predominance); (e) ulcerated EC. (2) *Enterocolitis* (*EC*) *with predominance of chronic changes*: (a) chronic atrophic EC (sprue-like atrophy in the small bowel; mucosecretory atrophy in the large bowel; (b) granular-cystic colitis (finely or grossly granular and ulcero-granular); (c) chronic ulcerative colitis; (d) chronic follicular EC. It is believed that a single type of lesion may be produced by different agents, and conversely that single agent may produce various types of lesions, which may occasionally be present at the same time in an individual patient.

Renal polycystosis induced by prednisolone tertiary butyl acetate in the newborn rat. R. W. Whitehouse, R. G. Lendon, and M. Lendon. Departments of Anatomy and Pathology, University of Manchester.

64 litters of newborn Sprague-Dawley rats were culled to 10 per litter shortly after birth. Seven from each litter were injected IM on the first day of extra-uterine life with either 66 mg/kg or 150 mg/kg prednisolone TBA (Codelcortone—TBA), and the remaining 3 with an equivalent volume of isotonic saline. Animals were killed on days 4, 8, 10, 12, 14, 16, and 20. The development of the induced renal cysts was studied histologically and histochemically. Cysts of the ampullae, collecting ducts, distal and proximal tubules, and glomeruli were found and their temporal sequence was determined. Quantitative estimation of glomerular numbers using an acid digestion technique showed a reduction of glomerular numbers in corticosteroid-injected animals, with apparently little new glomerulus development after day 8.

Influence of endogenous and exogenous factors on the morphology of lymphoid organs. J. Huber, E. Gelfand, and B. Wilson. Department of Pathology and Immunology, The Hospital for Sick Children, Toronto, Canada.

Lymphoid organs belong to a dynamic system and vary tremendously, both morphologically and functionally under different circumstances. As a consequence, the microscopical appearance may be deceptive and confusing. Major considerations in interpretation are: (1) the quantum expansion of the lymphoid system in the first few months of life; (2) the changes in the microenvironment such as local infections that affect regional nodes; (3) the generalised changes in response to systemic infection, chronic illness, and drug administration—for example corticosteroids, and (4) the limited capacity for routine histological stains in assessing functional status. Examples of developmental and acquired changes will be illustrated by comparing neonatal with postneonatal lymph nodes, also of lymph nodes from infected and noninfected sites, and lymph nodes before and after corticosteroid treatment. Finally, comparison will be made of thymus from biopsy and necropsy. These examples emphasise the caution with which static histological appearances must be interpreted, and the necessity to evaluate complete clinical information before drawing final conclusions.

Multiseptate gallbladder in cystic fibrosis. M. F. Kamal. Department of Pathology, University of Manchester.

Granular-cystic colitis. Pathological changes seen in infants with persistent or chronic diarrhoea in Rio de Janeiro. K. Madi, C. M. Ávila, E. T. D. Ávila, and D. de Paola. Departamento de Patologia, Universidade Federal do Rio de Janeiro, Brazil.

18 cases were selected from 380 necropsies on children with persistent (>15 days) or remittent diarrhoea. The mucosa presented a granular aspect with cysts. The lesions were graded *finely granular*, *grossly granular*, or *ulcero-granular*. In the first two forms, ulcerations could be detected only under the dissecting microscope or histologically. The appearances can be distinguished from the so-called colitis cystica superficialis seen in pellagra. The pathological picture is quite different from chronic ulcerative colitis of older children or adults, and from nodular lymphoid hyperplasia. Pathogenic micro-organisms were detected in only a few cases. Not uncommonly acute (necrotic) and chronic lesions are associated. All children examined had severe (protein-calorie) malnutrition but not necessarily pellagra. The authors believe this to be a non-specific reaction of the large bowel to prolonged action by one or several noxious agents, having malnutrition as a background.

Mucucutaneous candidiasis complicating neonatal intensive care. P. J. Kelehan and A. J. Barson. Department of Pathology, St Mary's Hospital, Manchester.

Three infants are described who died with widespread *Candida albicans* infection of the skin, and intestinal and respiratory tracts. They were 27–30 weeks in gestational age and survived from 10 to 27 days. All were treated in an intensive care unit for respiratory difficulty and jaundice, and all required mechanical ventilation and exchange transfusions. One infant died of necrotising enterocolitis, another of intraventricular haemorrhage, and the 3rd primarily of the candidiasis. A desquamative, erythematous rash covered the skin over most of the thorax and abdomen. It is thought that the infection began initially beneath elastoplast required for securing umbilical catheters, spreading elsewhere either via the umbilical vessels or the endotracheal tube. All were treated for bacterial sepsis and all showed extreme thymic involution. Such generalised mucocutaneous candidiasis appears to be a particular complication of prolonged intensive care of the ill premature infant.

Examination of the abortuses resulting from prenatal diagnostic surveillance for neural tube malformations. K. M. Laurence and J. O. Dew. Welsh National School of Medicine, Cardiff.

Antenatal diagnosis of the congenital nephrotic syndrome. A. H. Cameron, M. Crawley, H. O. Nicholson, D. I. Rushton, and R. H. R. White. Birmingham Children's and Maternity Hospitals, Birmingham.

The mononuclear phagocyte system—a hitherto unrecognised precursor cell. I. I. Smith, A. E. Dewar, and A. E. Stuart. Departments of Pathology, Royal Hospital for Sick Children, Edinburgh, and Universities of Edinburgh and Newcastle.

It is now established that the concept of a *reticulo-endothelial system* is erroneous. Numerous experiments on animals in different centres, including our own, have shown that phagocytosis of large particles is a property of tissue macrophages and circulating monocytes, which is not shared by endothelium or the fictitious 'reticulum cell'. Our studies in man of idiopathic thrombocytopenic purpura and autoimmune haemolytic anaemia confirm this. The modern concept of a *mononuclear phagocyte system* envisages tissue macrophages as being derived from circulating monocytes, and ultimately from bone marrow precursor cells. It does not preclude the possibility of local replication of macrophages, but relegates this to a minor role, at least under normal and most experimental conditions. Nevertheless, the failure to observe orthodox blood monocytes transforming into Kupffer cells has led to controversy regarding this generalisation. Our studies in mice treated with the simple lipid cholesterol oleate first showed a cell type, apparently transforming into Kupffer cells, that lacked the morphological or cytochemical characteristics of orthodox monocytes. Subsequently, this was also observed in untreated mice. Ultrastructurally, this cell resembles a lymphocyte before it undergoes this transformation. It can be suggested that this lymphocytoid cell is the true promonocyte and that this hitherto unrecognised cell plays a more general role in repopulating tissues with macrophages.

Functional control of fetal lung growth. J. S. Wigglesworth and R. Desai. Institute of Child Health, Royal Postgraduate Medical School, Hammersmith Hospital, London W12 0HS.

Improved lung expansion in premature newborn rabbits after tracheal instillation of synthetic surfactants. G. Grossmann and I. Larsson. Department of Paediatric Pathology, Karolinska Institutet, and the Swedish Institute for Surface Chemistry, Stockholm, Sweden.

Earlier experiments have shown that neonatal lung expansion can be facilitated by tracheal instillation of 'natural surfactant', containing phospholipids (8 mg/ml) and protein (0·6 mg/ml). In order to analyse whether the surface properties of natural surfactant can be imitated by a protein-free synthetic lipid preparation, lipids normally present in the fetal pulmonary fluid at term were analysed in various combinations with the pulsating bubble technique. An emulsion comprising 8 mg dipalmitoyl phosphatidyl choline, 2 mg phosphatidyl glycerol, 0·1 mg palmitoyl lysophosphatidyl choline, and 5 mg palmitoleic acid in 0·02 ml soy bean oil and 1 ml saline was found to have *in vitro* surface properties similar to those of natural surfactant. In subsequent experiments, 50 μl of the natural or the synthetic surfactant preparation were instilled in the trachea of premature rabbit neonates, delivered on day 27 of gestation (term = 31 ± 1 days). Pressure/volume recordings showed significantly increased pulmonary distensibility and improved stability on deflation in both treated groups, compared with untreated controls. The recordings from neonates treated with the synthetic preparation were similar to those obtained from litter-mates receiving natural surfactant. These findings suggest that tracheal instillation of such a protein-free synthetic lipid emulsion at birth might be used as a prophylaxis against respiratory distress in premature infants.

Effects of pulsed steroids and plasmaphoresis on a case of proliferative glomerulonephritis with crescents evaluated by renal biopsies. C. R. Tribe and G. B. Haycock. Southmead Hospital, Bristol.

Size of renal glomeruli in children with congenital heart disease and in unexpected deaths in infancy. S. Variend. Children's Hospital, Sheffield.

Large renal glomeruli have previously been associated with congenital cyanotic heart disease. The precise mechanism for the glomerulomegaly is still not clear, but one theory suggested is chronic hypoxia. The measurement of the size of glomeruli in a large number of cases of cyanotic congenital heart disease, 'cot death', and cases not apparently associated with chronic hypoxia was prompted by the suggestion that chronic hypoxia may be an important underlying mechanism in 'cot death'. 400 cases ranging in age from one week to one year were studied. In each case the areas of 10 glomeruli were measured from the mid-cortex in standardised normal sections. Tracings were made of the projected images of the glomeruli at constant magnification and the areas measured with a planimeter. This study confirms the presence of large glomeruli in many cases of cyanotic congenital heart disease, and concludes that a small but significant proportion of cases of 'cot death' also have large glomeruli. Some cases of endocardial fibroelastosis also showed a similar lesion. It is suggested that, while chronic hypoxia may be responsible for the glomerular enlargement, the elucidation of the precise mechanism responsible might help more in our understanding of 'cot death'.

Prune belly syndrome. R. N. Laurini and E. Gray. Royal Hospital for Sick Children, Glasgow, and University of Abderdeen.

Prune belly syndrome (PBS) is a rare entity classically described as a triad of absence or hypoplasia of abdominal muscles, urinary tract abnormalities, and cryptorchidism. The condition is almost entirely limited to males and can be associated with anomalies of other organs. Chromosomal anomalies are exceptional and only twice PBS has been reported affecting a family. We report the findings in 11 cases of PBS in males, including family history, chromosomal studies, and placental findings in some of the cases.

Congenital ciliary anomalies and respiratory disease. J. M. Sturgess, J. Chao, and J. A. P. Turner. The Hospital for Sick Children, Toronto, Canada.

The mucociliary clearance mechanism in the lung is dependent on the propulsive force of cilia to promote the flow of mucus in the respiratory tract. Recent evidence has implicated specific defects in cilia as the basis of human respiratory disease, such as that seen in Kartagener's syndrome. Two types of defect were identified at the ultrastructural level in the human ciliary axoneme. The lack of dynein arms on the outer microtubular doublets of the ciliary axoneme is described and results in immotile cilia. Recently, we found a second abnormality in human cilia, a defect in radial spokes which is identified by the altered radial symmetry of the ciliary axoneme and the eccentric central tubules and sheath. Both defects are considered to be congenital anomalies of cilia. These defects cause ciliary dysfunction and result in similar clinical consequences of chronic upper and lower respiratory disease from early childhood either alone or as the triad of chronic sinusitis, bronchiectasis and situs inversus, characteristic of Kartagener's syndrome.

Abnormalities of the complement system in children with liver disease. V. F. Larcher, J. Wyke, A. P. Mowat, and R. Williams. Department of Child Health and Liver Unit, King's College Hospital, London SE5.

Abnormalities of the complement system have been described in adult liver disease (Charlesworth *et al.*, 1977). We studied both classical and alternate pathways of complement in 84 children with liver disease and in 30 control children. Classical pathway components were measured by haemolytic or immunodiffusion techniques. Alternate pathway activity was measured by determination of yeast opsonisation index (0·1 = mean number of yeasts phagocytosed per normal polymorph in presence of test serum; Soothill and Harvey, 1977). High values of yeast opsonisation ($P<0·001$) were found in 10 preoperative cases of biliary atresia (0·1 = 5·38 ± 0·70 mean ± 2 SD) compared with controls (4·3 ± 1·16 mean ± 2 SD). Defective opsonisation (0·1 = 1·66 ± 1·16 mean ± 2 SD; $P<0·001$) and low levels ($P<0·001$) of complement factors, 3, 4, 5, B, and D were found in 10 children with fulminant hepatic failure. Normal values were found in 2 survivors and in 4 children with previous hepatic failure. Eight further patients (2 after successful surgery for biliary atresia; 2 untreated chronic active hepatitis; 4 corticosteroid-treated chronic active hepatitis) had defective opsonisation with or without changes in other complement components.

Serum complement abnormalities are common in children with liver disease, but more study is necessary to elucidate their role in pathogenesis of liver disease or its complications.

Hepatic collagen synthesis and its modification by colchicine in a rat model of cirrhosis of the liver. M. S. Tanner, D. Jackson, and A. P. Mowat. Department of Child Health, King's College Hospital Medical School, Denmark Hill, London SE5.

An animal model of hepatic cirrhosis, in which rats pretreated with oral phenobarbitone inhale carbon tetrachloride twice weekly, was used to study hepatic collagen synthesis and its modification by colchicine. Hepatic collagen, measured as protein-hydroxyproline, doubled after 4 weeks' exposure, and free proline increased concomitantly. The activity of peptidyl prolyl hydroxylase (PPH), an enzyme catalysing an early step in collagen synthesis, increased approximately 5-fold, and this higher activity preceded the increase in collagen, PPH activity showed considerable lability, an increase in activity occurring between 24 and 48 hours after each exposure to carbon tetrachloride. Colchicine, 100 μg given daily by orogastric tube, for 6 days a week, partially prevented this collagen deposition. The liver collagen content, in μmol hydroxyproline /g wet liver, for control rats was 1·007 ± 0·109; for rats given 4 weeks' carbon tetrachloride it was 2·086 ± 0·416; for rats given 4 weeks' carbon tetrachloride and colchicine it was 1·309 ± 0·077. PPH activity was similar in the last two groups. Colchicine treatment did not affect growth.

Colchicine, which decreases net collagen deposition both by microtubular inhibition and by stimulating collagenase, may impede the progression of chronic liver disease to cirrhosis.

Renin and angiotensin in normal, prepubertal girls. O. R. C. Smales, F. Broughton Pipkin, and M. O'Callaghan. Departments of Child Health and Obstetrics and Gynaecology, City Hospital, Nottingham.

Renin and angiotensin II (AII) levels were measured in 30 normal girls, 2 to 11 years old. The older girls had lower plasma renin concentrations (PRC) which were not significantly different from adult levels. Plasma AII levels however were significantly higher in all children ($P<0\cdot001$). PRC and AII levels were lower when diastolic blood pressure was greater than 70 mmHg than when it was less than 70 mmHg. This difference was only statistically significant for PRC.

Regression analysis showed that plasma renin activity was inversely related to serum sodium levels and directly proportional to the ratio serum sodium:potassium ($P<0\cdot025$ for both). PRC was also proportional to serum potassium ($P<0\cdot02$). Plasma AII was inversely proportional to serum sodium ($P<0\cdot025$) and related to PRC ($P<0\cdot05$).

Simultaneously measured renin and AII levels have not, to our knowledge, been previously reported for this age group. The results show that the high levels seen in infancy remain above adult levels during the first few years of life. However, it appears that the stimuli of relative hypotension and hyponatraemia are controlling factors at these ages as well as in adulthood.

•

Which 'small-for-dates' infants are malnourished? O. G. Brooke and Fiona Butters (introduced by R. J. West). Department of Child Health, St George's Hospital, London SW17.

In an attempt to improve diagnostic precision in assessing small-for-dates babies, we measured upper arm muscle and fat area (derived from mid-upper arm circumference and skinfold measurements) in 221 unselected term neonates. Results were expressed per unit upper arm length. Irrespective of birthweight, infants were defined as 'malnourished' if arm muscle *and* arm fat areas fell more than 1 SD below the mean, or if either area alone fell more than 2 SDs below the mean. By these criteria, 22 infants were malnourished (birthweight range 2100–3570 g). A further 21 infants were small-for-dates by current definition, being <10th centile of weight for gestational age, but not malnourished. We called these 'normal small infants'. There was a predominance of Asians in each group. 14 out of the 22 'malnourished' infants had obstetric complications which could impair fetal growth (hypertension, APH, toxaemia, anaemia). Only one of the 'normal small infants' had any such complications. These differences were highly significant ($P<0\cdot001$). Skinfold measurements alone gave poor discrimination between 'malnourished' infants with a bad obstetric history and 'normal small infants' without obstetric complications. Birthweight only identifies the grossest forms of intrauterine malnutrition and should no longer be the sole criterion for defining the small-for-dates baby.

Circadian rhythms of melatonin and cyclic-AMP in neonates. A. Evans,* N. D. Carter,* O. G. Brooke,* and J. Smith.† Department of Child Health, St George's Hospital Medical School, London SW17 0RE* and the School of Pharmacy, University of Bradford.†

Circadian variations in blood and urine levels of cyclic-AMP (Holmes and Hamadah, 1977) and melatonin (Wurtman and Moskowitz, 1977) is well documented, and the melatonin rhythm is maintained in pregnant women (Matthews *et al.*, 1978). We investigated these rhythms in neonates and attempted to assess the influence of maternal circadian activity of melatonin on rhythm development in the baby. Blood was taken for serum melatonin estimation from the umbilical cords of 26 normal term infants, and paired samples of cord and maternal blood samples were taken from a further 20 normal infants. Melatonin was measured by radioimmunoassay. Cord blood from another 71 term normal infants was assayed for cyclic-AMP by a competitive protein binding assay.

The results of 26 cord blood melatonin assays (Table 1) show a clear circadian rhythm. The daytime (0800–2000 hours) levels are significantly lower than the night-time (2000–0800 hours) ones ($P<0\cdot05$). Assay of the paired samples showed no significant correlation between cord and maternal serum melatonin levels. The maternal levels showed no carcadian rhythm.

Cord serum cyclic-AMP levels showed a circadian rhythm (Table 2). The morning (0000–1200 hours) levels are significantly greater ($P<0\cdot001$) than the evening (1200–2400 hours) ones.

Table 1 *Melatonin levels of 26 term infants*

Hours	2400–0400	0400–0800	0800–1200	1200–1600	1600–2000	2000–2400
n	3	2	4	8	3	6
Melatonin pg ml^{-1} (mean ±1 SD)	61·7± 55	3·5± 4·9	4·0± 8·0	15·0± 24·2	1·3± 2·3	37·3± 29·5

Stools in infancy. Frequency and weight, water, and energy content. N. Lemoh and O. G. Brooke. Department of Child Health, St George's Hospital, London SW17.

There is little information on the frequency of defecation in normal infants and toddlers and on their stool weight, water, and energy content. This study was undertaken to provide such data without any attempt being made at energy balance study.

Stools were collected in rayon napkin liners during a period of 3–9 days from 53 healthy infants and toddlers aged 3 days to 2 years, who were either in their own homes or in hospital as social admissions. Those in hospital were given a reasonable period for adjustment before being studied. In a preliminary study a method of stool collection was established. The aim of this was to observe the effect on weight of wet stools exposed to wet napkins. Preweighed samples of wet stools in liners were incubated at room temperature for 2 hours in previously weighed disposable napkins adequately soaked with 0·9% saline solution. The result showed no significant change in stool weight or napkins. Subsequently, freshly passed stools were frozen at −24°C, weighed wet, freeze-dried for estimation of water content and for determination of total daily energy content. Neonates were all bottle fed and older infants were on a mixed diet. Infants with gastrointestinal disorders or other illness were excluded.

Results are given in the Table. There was a progressive decrease in stool frequency with age but there were wide variations between individuals. There was also marked variation in daily stool weight but little fluctuation in stool water content. The stool energy concentration tended to fall with increasing age.

Table *Stools in normal infants (mean, observed ranges, and SD of various measurements)*

	Age		
	3 days–4 weeks	*1–12 months*	*12–24 months*
No. of infants	25 (22*)	11 (8*)	17 (12*)
Interval between stools (hours)	6·8 (3–20)	11 (7–36)	15 (7–43)
Daily mean wet weight (g)	26 (4·6–58)	31 (19–70)	71 (14–133)
% water	73±4·2*	75±3*	74±4*
Daily mean energy per gram (kcal)	7·7* (5·2–12·6)	6·6* (4–11·7)	6·0* (2–10)
Total daily mean energy (kcal)	46·7* (22–93·7)	43·7* (11–73)	62* (10–130)

Adhesion of Escherichia coli (EC) to buccal epithelial cells (BEC). D. C. A. Candy, J. Chadwick, W. C. Marshall, and J. T. Harries. The Hospital for Sick Children, Great Ormond Street, London WC1N 3JH, and Institute of Child Health, Guilford Street, London WC1.

The pathophysiological mechanisms operating in diarrhoeal states are currently under intense study, and this is particularly the case for the mechanisms involved in the adhesion of bacteria to epithelial cells: adhesion to epithelial cells is a prerequisite to intraluminal colonisation and the subsequent sequence of events which induce small intestinal secretion and diarrhoea. We studied adhesion of EC to human BEC using a modification of the method of Ofek *et al.* (1977).

We established that a strain of EC (026:K60) known to adhere to fetal intestine (McNeish *et al.*, 1975) also adhered to BEC, and that another non-adhesive strain failed to do so. Colonies of EC were isolated from the stools of 13 healthy infants, and 2–6 colonies in 10 of these infants were the nonadhesive organisms (4 of these strains were designated as 'enteropathogenic' on the basis of their agglutinating properties). Agglutinable EC isolated from the stools of 9 children with diarrhoea were studied and 8 were adherent to BEC. Adhesion was partially or completely inhibited by D-mannose, and EC isolated from 2 patients with diarrhoea adhered to their own BEC but not to donor cells.

These results suggest (1) 'enteropathogenecity' of EC is not synonymous with their agglutination properties, (2) EC binds to specific mannose-like receptor sites, and (3) the BEC system may be a simple test to assess whether a bacteria is 'enteropathogenic'.

Enteropathogens in preschool children and their pets. R. W. Newton, R. J. Pugh, and I. D. Leighton (introduced by T. Turner). Department of Paediatrics and Bacteriology, Hull Royal Infirmary, Anlaby Road, Hull.

During a 4-month period, 152 consecutive preschool children attending a general outpatient clinic were screened for intestinal parasites and enteropathogenic bacteria. Each child was requested to submit 3 fresh stool specimens and also 3 stool specimens from any animal with which the child had significant contact. Careful record was made of age, social class, type of accommodation, and history of pica in the child. Inquiry was made into the health of any pet.

Of 78 children with no family pets, 34 (44%) failed to submit specimens, while 23% submitted 3 specimens. Only one child of the 44 submitting specimens had a significant culture. 74 children with pets entered the study; 51 (60%) failed to submit specimens while 12 (16%) produced 3 specimens. Among the 23 children submitting specimens 2 were found to have *Giardia lamblia*, one pathogenic *Escherichia coli*, and one *Salmonella typhimurium*. 12 dogs had stools submitted; 2 were infestated with *G. lamblia*, while a 3rd had *S. typhimurium*. Two children associated with these pets had recurrent diarrhoea, while a 3rd had the same pathogen (*S. typhimurium*). Other animals including cats, budgerigars, and rabbits failed to produce any positive pathogens.

This study shows the difficulty of patient and pet compliance and confirms that the presence of enteropathic bacteria and other parasites is more likely in children in regular contact with family pets, although both the children and pets may well be asymptomatic.

Nebulised salbutamol in the treatment of acute asthma in children. J. B. G. Watson and Olga M. Bannister. Departments of Paediatrics and Physiotherapy, Children's Hospital, Sheffield S10 2TH.

A PGS compressor unit with a Bird's nebuliser was used to administer nebulised salbutamol or placebo to a group of children with acute asthma in a double-blind trial. The salbutamol group showed a greater rise in peak expiratory flow rate (PEFR) (67 l/min) compared with the placebo group (21 l/min) $P<0 \cdot 005$. A further 57 patients had 190 doses of nebulised salbutamol and the mean rise in PEFR was 55 l/min. When IPPB was used to administer the nebulised solutions, the salbutamol group showed a mean rise in PEFR of 50 l/min compared with 10 l/min in the placebo group. Salbutamol administered by nebulisation offers an effective alternative to parenteral treatment for children with asthma. As a result of nebulised treatment fewer children required parenteral therapy in 1977 compared with 1975.

Bronchodilator effects of nebulised chlorpheniramine in childhood asthma. R. C. Groggins, A. D. Milner, and G. M. Stokes. Queen's Medical Centre, Nottingham.

Previous workers have failed to demonstrate a bronchodilator response to antihistamines in childhood asthma, in doses which did not produce side effects. However, a study on adult asthmatic subjects has shown that chlorpheniramine delivered intravenously is an effective bronchodilator (Popa, 1977). We investigated the effect of nebulised chlorpheniramine in a group of 10 asthmatic children aged between 8 and 14 years (mean 11). Response to treatment was measured with a Wright's peak flow meter and FVC and $FEV_{0 \cdot 75}$ were measured using a Morgan wet spirometer. Measurements were made before and for 2 hours after inhalation of the drug. At the end of 2 hours the children inhaled nebulised salbutamol (5 mg in 2 ml water) and lung function tests repeated after 15 min. Children attended on 3 occasions and received 2, 4, and 8 mg chlorpheniramine successively.

Bronchodilatation was observed, usually within 2 min of the inhalation of chlorpheniramine, and reached a plateau by 45 min. The response to 4 and 8 mg was similar with a greater than 30% improvement in $FEV_{0 \cdot 75}$ and PEFR response to 2 mg was less dramatic, with improvements of 15–20%. The only side effect was that of coughing, and each patient coughed at least once.

Antihistamines if delivered by appropriate routes and in appropriate doses do produce bronchodilatation in children with asthma.

Hyposensitisation in house dust mite sensitive childhood asthma. J. O. Warner, J. F. Price, and E. N. Hey. Respiratory Unit, The Hospital for Sick Children, Great Ormond Street, London WC1N 3JH.

Hyposensitisation with *Dermatophagoides pteronyssinus* tyrosine absorbate in asthmatic children shown to be *D. pteronyssinus* sensitive by bronchial provocation tests (BPT), was shown to be effective in a double-blind controlled trial. Treated children (27) used less medication while maintaining clinical and lung function improvement compared with controls (24). These children responded to *D. pteronyssinus* injections alone despite the fact that most reacted to other inhalant antigens on prick skin tests. This confirms that *D. pteronyssinus* is the predominant antigen responsible for asthma in British children. In most children the benefit occurred despite no change in immediate response on BPT but the late reaction was lost in half the patients and these patients had the greatest symptomatic improvement. This confirms the importance of late reactions in childhood asthma.

Postprandial total serum bile acid concentrations in cystic fibrosis. Bryan J. Starkey and Mary C. Goodchild.Department of Clinical Chemistry, Queen Elizabeth Hospital, Birmingham B15 2TH.

The efficacy of a single 2-hour postprandial total serum bile acid (t.s.b.a.) concentration in the early detection of liver disease in cystic fibrosis (CF) was assessed. 27 CF patients (aged 4–27 years), 21 age-matched controls, and 40 healthy adults (aged 19–52 years) were studied. Venous blood samples were drawn in the morning, 2 hours after ingestion of a weight-related chocolate stimulus. T.s.b.a. concentrations were determined by the method of Mashige *et al.* (1976) and conventional serum liver function indices by standard methods. T.s.b.a. concentrations expressed as mean ± 1 SD (μmol/l) were: 27·0 ± 26·4 (CF patients), 19·9 ± 5·5 (age-matched controls), and 17·3 ± 4·5 (healthy adults). Most CF patients, therefore, had normal t.s.b.a. concentrations.

Six results in the CF group deserve comment: 2 patients with established liver disease did have abnormally high t.s.b.a. concentrations of 56·0 and 150·0 μmol/l; 3 patients with t.s.b.a. concentrations within the normal range were thought, by other criteria, to have liver disease; one patient, in whom the t.s.b.a. concentration was raised (42·0 μmol/l) had no other finding suggestive of liver involvement.

Thus, a single 2-hour postprandial t.s.b.a. concentration appears not to be particularly informative in CF. Wider investigations of bile acid metabolism, including sequential studies, may be necessary to elucidate the size and distribution of the bile acid pool, at varying ages, in this disease.

Release of endogenous secretin in children with cystic fibrosis. J. McKiernan, J. King, E. J. Hiller, and D. Johnston. Department of Child Health, Nottingham University, and The City Hospital, Nottingham.

The introduction of acid to the duodenum, in health, results in a brisk rise in plasma secretin levels. This endogenous secretin stimulates pancreatic secretion of water and bicarbonate, which neutralises the duodenal acid and inhibits further secretin release. As most children with CF have pancreatic exocrine insufficiency, we studied the pattern of secretin release in this condition. Nine children with CF were studied, all of whom were considered to have pancreatic exocrine insufficiency. Two different acidic drinks were given—0·2 M citric acid and 20% glucose, and pure lemon juice. Plasma secretin was measured before and after the drinks by radioimmunoassay. In only one case was there basal hypersecretinaemia (i.e. >60 pg/ml). The children who received the citric acid and glucose mixture showed a mean basal and mean peak plasma secretin of 37 and 120 pg/ml respectively. The values in the children who took citric acid alone were 34 and 48 pg/ml respectively. Thus both groups showed a positive response which was significantly greater in the citric acid and glucose group ($P<0·05$). These preliminary studies provide some new information of the regulation of pancreatic secretion in disease.

Bronchial allergy in children with cystic fibrosis. J. F. Price, P. H. Weller, S. A Harper, and D. J. Matthew. Respiratory Unit, The Hospital for Sick Children, Great Ormond Street, London WC1N 3JH.

Patients with cystic fibrosis have a high prevalence of positive skin prick tests to common inhaled antigens, but the importance of bronchial allergy in the disease is uncertain. We have investigated the response to antigen inhalation and exercise, and symptoms of respiratory allergy in a group of children with CF. 10 of 15 CF children with positive skin tests gave an immediate bronchial response to the antigen inhaled, 5 of them also gave a late (4–8 hour) response; however only one gave a history of asthma. In 6 patients tested with *Aspergillus fumigatus* the bronchial response varied, 2 were negative, one gave an immediate response, and 3 gave a dual (immediate and late) response. None of the children showed the characteristic pattern of response to exercise seen in asthmatic patients, an initial rise in peak flow rate (PFR) followed by a fall of greater than 14% below the resting level. Two patients showed an abnormal rise in PFR during exercise, a pattern previously described in CF.

The results suggest that bronchial allergy, immediate and late, does not completely explain susceptibility to asthma, and that other factors including perhaps the type of bronchial reactivity shown by bronchoconstriction after exercise may be required.

Growth patterns in children with malignant disease. N. K. Griffin and Jane Wadsworth. The Hospital for Sick Children, Great Ormond Street, London WC1N 3JH, and St Bartholomew's Hospital, West Smithfield, London EC1A 7BE.

Short stature has been described as a complication of malignant disease in childhood. We studied 71 children with leukaemia and 24 with extracranial solid tumours and compared their growth with normal children for age and sex. Variables studied included diagnosis, radiotherapy field and dose, duration of chemotherapy, and the patient's age and sex. Children with leukaemia grew at a reduced rate in the year after presentation, and had a mean height after one year that was 0·41 SDs below their value at presentation ($P < 0 \cdot 001$). This effect was related to cranial and craniospinal irradiation, and was particularly pronounced after craniospinal irradiation. After one year from presentation growth rate was normal in all groups of patients, with no evidence of 'catch-up growth'. Failure of normal growth in the first year of treatment was observed in 59 of 65 patients who had received cranial or craniospinal irradiation.

It is concluded that prophylactic central system irradiation in leukaemic children causes a transient reduction in growth rate, but that the effect on eventual height attained is likely to be small.

Investigation using psychological tests in children with recurrent abdominal pain of nonorganic cause. R. H. Davies, St David's Hospital, Bangor, and E. Knassel, Department of Psychology, University College of North Wales, Bangor.

Twenty children with recurrent abdominal pain of nonorganic cause were compared with 20 children with appendicitis. They were subjected to Eysenk personality inventories, social maturity scales, the family relations test, the Rep test, and the self as implied pole test. Results showed the subjects were not different from the controls in the Eysenk extroversion/introversion or neuroticism tests. The subjects scored normally on the social maturity scales. In the family relations test they scored significantly lower than the controls in applying attributes and statements to themselves. In the Rep test they differed from controls in thinking themselves messy not tidy, failures not successes, but not unduly nervous. They scored significantly higher than the controls in the self as implied pole test. So the 'little bellyachers' were not neurotic, introverted, or socially immature, but although relatively confident they felt themselves untidy and failures; they dissociated attributes from themselves, and felt themselves poles apart from others.

Archives of Disease in Childhood, 1979, **54**, 166–167

Securing haemostasis during umbilical catheterisation in a neonate

Sir,
The most common method of maintaining haemostasis after catheterisation of umbilical vessels is to secure the catheter to the edges of the cord by using a nylon stitch. When the cord is initially cut to insert the catheter there may be some blood loss, and furthermore some blood may ooze at times in spite of a stitch. We recommend tying firmly a single knot at the base of the cord using wet ribbon gauze (15.2 × 1.0 cm). If this is done before the cord is cut, the catheters will pass without difficulty. Moreover should there be oozing from the cord the nursing staff have merely to tighten the knot before summoning medical help.

Henoch-Schönlein purpura after chickenpox

Sir,
Although Henoch-Schönlein purpura has been associated with many viruses, I have been unable to find a report of it after chickenpox.

An 8-year-old boy was admitted with a 36-hour history of abdominal pain, a tender right ankle joint, and a purpuric rash on his legs. 10 days earlier he had been unwell with a runny nose, sore throat, and cough, followed by a typical chickenpox rash, diagnosed by his family doctor.

On admission he complained of abdominal pain. He was apyrexial. There were a few submandibular nodes palpable and the tonsils were inflamed. Blood pressure was 110/70mmHg. There were scattered lesions over his back and anterior chest wall showing crust formation consistent with chickenpox. Over the buttocks and extensor surfaces of the legs he had a macular-purpuric rash and small haemorrhagic lesions. His right ankle joint was tender and slightly swollen. The platelet count was normal. There was a trace of proteinuria on the first day only.

The history, together with the physical findings, was typical of Henoch-Schönlein purpura.

He made an uneventful recovery during the next 4 days and has remained well since.

Incidence of dental caries in coeliac children

Sir,
As the result of comments made by parents at a Coeliac Society meeting to my paediatric colleague, Dr J. Kuzemko, concerning the rate of decay of their children's teeth, I have reviewed the developing dentitions of 12 of the coeliac children under his care at Peterborough during the last 5 years, for tooth quality and incidence of dental caries.

Coeliac disease was diagnosed at ages ranging from 6 months to 13½ years, and the children have been on a gluten-free diet for between 3 and 11 years. This is a small sample, but the caries experience of this group of children was certainly no worse than one would expect in a similar group of normal local children. Only one case of gross caries of the deciduous dentition was found, and the parent confessed to plying the child with sweets to compensate for the restricted diet. Thus a gluten-free diet does not appear to affect the quality of the developing teeth as far as caries resistance is concerned.

What does have an effect is if the condition is not diagnosed correctly soon after its onset in the early months or years, as the severe constitutional disturbance causes hypoplasia of those areas of the crowns of the permanent teeth which are calcifying at that time. During the first year this affects the anterior teeth and first molars, and these hypoplastic areas are prone to decay and spoil the appearance of the teeth.

We should be interested to learn of the experience of others in this perhaps neglected area.

Atypical PKU with normal phenylalanine hydroxylase and dihydropteridine reductase activity *in vitro*

Sir,
In a recent report (*Archives*, 1978, **53**, 674) Schaub *et al.* described a patient with phenylketonuria who had normal hepatic activity of phenylalanine hydroxylase and dihydropteridine reductase. The patient responded to the administration of tetrahydrobiopterin (the natural cofactor of phenylalanine hydroxylase) by a rapid fall in plasma phenylalanine levels, and the authors postulate that their patient has a defect of biopterin synthesis.

Evidence for the existence of such a defect was obtained in two cases (those of Dr F. Rey in Paris and Dr K. Bartholomé in Heidelberg) who showed reduced serum and urine levels of total biopterin derivative (measured by *Crithidia fasciculata* assay) and an abnormal pattern of pterins on chromatography (Leeming *et al.*, 1976). The results of the *Crithidia* assays carried out by one of us (R.J.L.) in 1975 on the patient of J. Bartholomé (Kaufman *et al.*, 1975; Bartholomé *et al.*, 1977) have not been published and we should like to present them (Table).

Table *Levels of total biopterin derivative measured by Crithidia fasciculata assay in a patient with phenylketonuria (Bartholomé et al., 1977). Comparison with control values (mean ± SD)*

Subjects	*Serum* (µg/*l*)	*Urine* (*mg/l*)	*Liver (ng/g wet weight)*
Patient	0·2 0·7	0·09	16·7
Adult liver stored identically	—	—	550
Children with 'classical' PKU on diet	4·86±3·03	2·46±1·76	—
Normal children	1·78±0·79	—	—
Normal adults	1·81±0·64	2·1±1·32	—
Adults at abdominal operation	—	—	375±232

The levels of total biopterin activity in liver are markedly reduced, as are the levels in serum and urine. These results suggest that the patient, like that of Rey *et al.* (1977) and another reported recently by Kaufman *et al.* (1978), is deficient in biopterin. It remains to be explained why other measurements of hepatic cofactor activity failed to demonstrate an abnormality in Dr Bartholomé's case (Kaufman *et al.*, 1975; Bartholomé *et al.*, 1977).

Mr Leeming thanks Dr Bartholomé for allowing investigation of the patient.

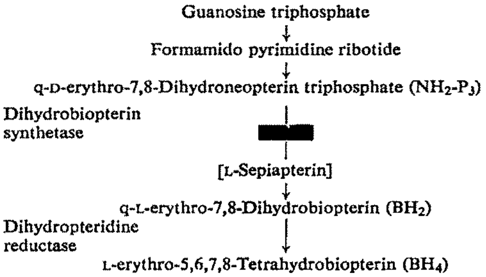
Dr Schaub and co-authors comment:

In our Short Report (*Archives*, 1978, **53**, 674), it was not our intention to claim the first description of a defect of biopterin synthesis. We only wanted to show that tetrahydrobiopterin (BH_4) can be absorbed from the gut and can be applied to lower the blood phenylalanine level in atypical PKU due to a suspected defect of biopterin synthesis.

Nevertheless, in the meantime we have been able to localise the metabolic block in our patient (Niederwieser *et al.*, 1979). Using high-voltage paper electrophoresis we found large amounts of neopterin in urine but no trace of biopterin or L-erythro-7, 8-dihydrobiopterin (BH_2). A comparable decrease of serum phenylalanine was observed after an oral administration of either BH_4, BH_2, or L-sepiapterin (Curtius *et al.*, 1979). The last is postulated to be an intermediate in the biosynthesis (Eto *et al.*, 1976; Gal *et al.*, 1978) of BH_2 from D-erythro-7,8-dihydroneopterin triphosphate (NH_2-P_3). Therefore, the metabolic block in this child must be between NH_2-P_3 and L-sepiapterin (Figure).



Guanosine triphosphate
Formamido pyrimidine ribotide
q-D-erythro-7,8-Dihydroneopterin triphosphate (NH₂-P₃)
Dihydrobiopterin synthetase
[L-Sepiapterin]
q-L-erythro-7,8-Dihydrobiopterin (BH₂)
Dihydropteridine reductase
L-erythro-5,6,7,8-Tetrahydrobiopterin (BH₄)

Book reviews

Primary Child Care. A Manual for Health Workers. By M. King, F. King, and S. Martodipoero. (Pp. 315; illustrated + tables. £2.00, soft cover.) Oxford University Press: London. 1978.

Maurice King's name became a byword in 1966 when he produced the 'Red Bible'—*Medical Care in Developing Countries.* Many would say that the production of this book was a turning point in the approach to health in developing countries. Since then Maurice King has written *Nutrition in Developing Countries* and a laboratory manual. Now, after a number of years of intensive work in Surabaya, he has brought out a book that may be more important in its direct effect than any of his previous writing. This new book is a system of primary care and is intended for adaptation and translation in whole or in part as one part of WHO's contribution to the International Children's Year—1979.

This book covers the diagnosis, understanding, and management of common conditions of childhood and, at the same time, shows how this can be built into a comprehensive system of child care with a necessary emphasis on prevention.

The author has taken great pains over detail in layout, choice of illustration, and simplicity of English. Although written for medical assistants it will be used by nurses, medical students, and doctors, many of whom in developing countries will for the first time possess their own book on child health, thanks to the low price of only £2.

This book is only part of a package or micro-plan and will be shortly followed by a teachers' guide which will contain 3000 multiple-choice questions and much other guidance material in the management of child health centres. Some 240 coloured transparencies of the common conditions so well managed in these books will also be available.

DAVID MORLEY

Surgical Conditions in Paediatrics. Postgraduate Paediatric Series. By H. Homewood Nixon. (Pp. 448; illustrated. £23.00, hardback.) Butterworth: London. 1978.

Is there any place today for the medical treatment of pyloric stenosis, or for local anaesthesia in its surgical treatment? What are the proved facts about the causation of intussusception, and what is the place of the barium enema in its diagnosis and management? What is the place, if any, for surgery in rectal prolapse, or in umbilical hernia? How to choose between the often very diverse treatments enthusiastically recommended for exomphalos? These are the sort of day-to-day questions about which the paediatrician so often longs to be able to button-hole a paediatric surgeon of experience and wisdom, and to pick his brains. Nixon's book, expressly written for medical paediatricians, goes a long way towards meeting this very need. His long experience at Great Ormond Street (his predecessor Denis Browne's aphorisms happily enliven and enlighten the text) is here distilled and in a most agreeable style. To cite one instance, if there is a more succinct and practical guide to the handling of the thorny subject of the undescended testicle, your reviewer has not met it. And as would be expected, the section on anorectal anomalie subject to which Nixon has contrib much, is beautifully lucid and pract Less so are only one or two sections, as the one on meconium ileus which to give a clear programme for hand these cases, or to explain when and the Gastrografin enema (described fir 1970 though here as 'recently') shoul used. Sternomastoid tumour, ano often debated condition, is not mentio perhaps being assumed to be nonsur anyway.

The illustrations are plentiful effective, the one on p. 371 sufficientl to have forced me to revise my hith simplistic teaching that there is no thing as tongue-tie.

DOUGLAS GAIRD

Shorter notice

Heart Disease in Infancy and Childh Third edition. Edited by J. D. K R. D. Rowe, and P. Vlad. (Pp. 1 illustrated + tables. £36.00, hardba Ballière Tindall: London. 1978.

A big welcome for the long awaited edition of this pioneering book! I bursting with new chapters and new id and for such a large book is remark up to date, containing many 1977 r ences. Some sections, and particularly approach to nomenclature, are ra confused, and many angiocardiogram poor. But the book remains a stan reference work, and a must for any lib of paediatrics or cardiology. Size apa could well be termed the paedi cardiologist's vade-mecum.

Lioresal®

Relieves spasticity due to

Multiple Sclerosis
Spinal Lesions

"... has become the agent of choice for the treatment of spinal spasticity..."[1]

"... drug therapy for spinal spasticity has been revolutionised by baclofen (Lioresal)."[1]

"... regarded by many as the drug of choice in the treatment of spasticity due to spinal cord lesions..."[2]

Now also indicated for

Spasticity associated with cerebral palsy
and other allied conditions

STATISTICS AT SQUARE ONE

by T. D. V. SWINSCOW

from the British Medical Journal

The statistical testing of data is indispensable in many types of medical investigation and a help on countless occasions in clinical practice. This book provides step-by-step instruction. Subjects covered include standard deviation, χ^2 tests, t tests, non-parametric tests, and correlation. The book includes sections on Fisher's exact probability test and rank correlation not published in the *B.M.J.* series. Methods specially adapted to pocket calculators.

"The ability to put symbols in sequence may well be one of the greatest advances in man's development . . . This excellent and attractive volume will give you an idea into which category an article or projected article fits. The ink you save may be your own. It is superb value."
O'Donnell, Barry, *British Medical Journal*, 1977, **1**, 451.

". . . this gem of a practical booklet squeezes the essence of biostatistics into 75 well-written, well-organized pages. Newcomers to the field will like the way obscure concepts are clarified; experts will find the book valuable as a teaching aid."
de Jong, Rudolph H., *J.A.M.A.*, 1977, 237, 1874

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42**, 109; 1973, **48**, 751).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged.
(11) References in the text. Papers with one or two authors: name author(s) on each occasion the paper is cited with year of publication in parentheses. Papers with more than two authors: use—*et al.* in each citation.
(12) References to be listed alphabetically with full title of article or book; title of journal to be given in full, first *and* last page numbers of journal articles to be given.
(13) Summary to be typed on a separate sheet; and it should say what was done, and what was concluded.

Notice to Advertisers

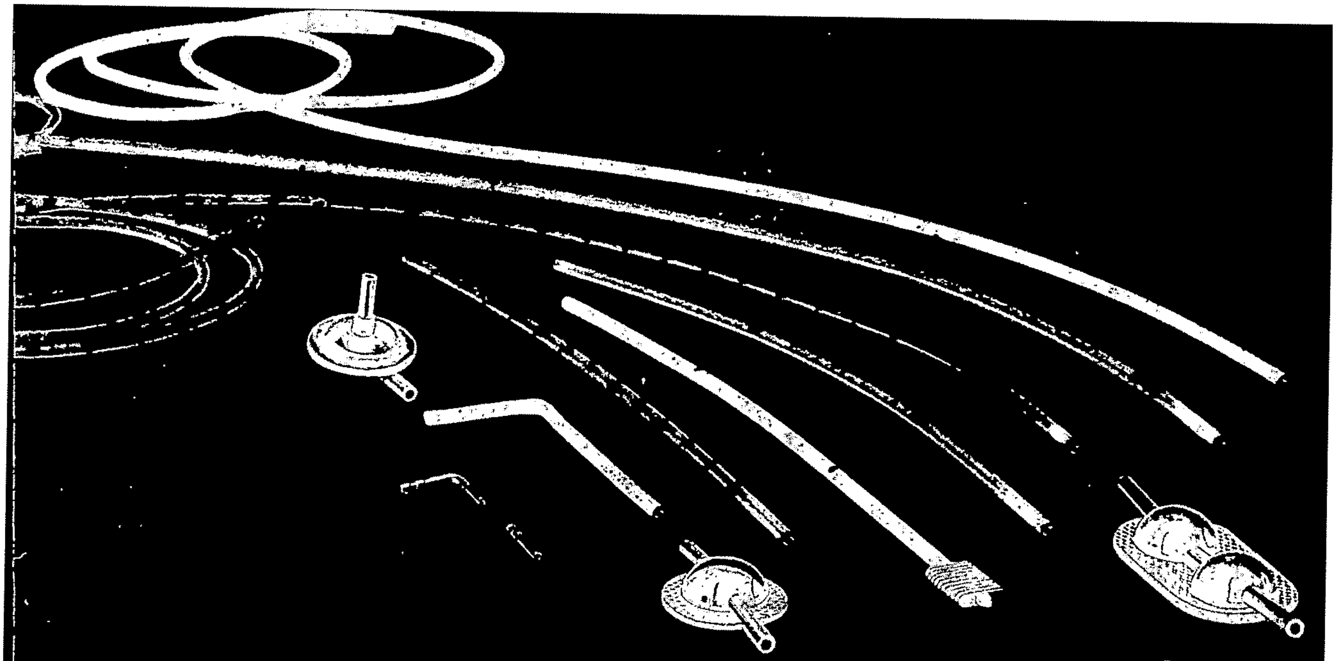
Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

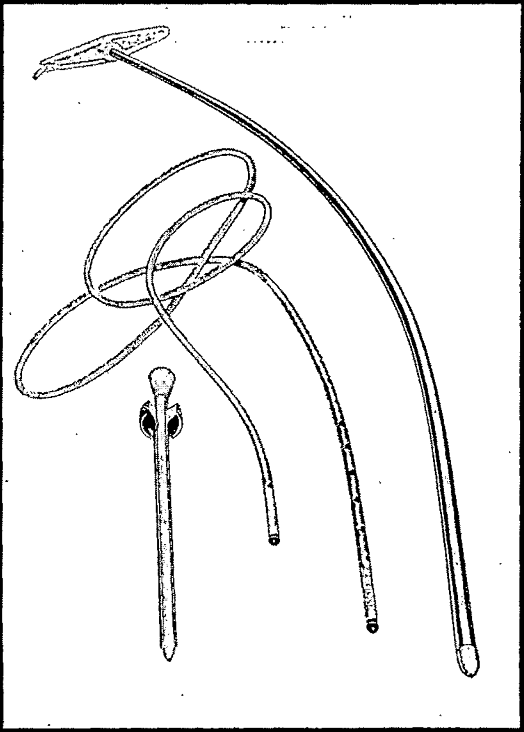
Archives of Disease in Childhood is published monthly. The subscription rate is £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

Apart from any relaxations permitted under national copyright laws, no part of this publication may be reproduced, stored in a retrieval system, or transmitted in any form or by any means without the prior permission of the copyright owners. Permission is not, however, required to copy abstracts of papers or of articles on condition that a full reference to the source is shown. Multiple copying of the contents of the publication without permission is always illegal.



Simplicity itself



The Codman Shunt range, available only from Downs, has proved outstandingly popular with British surgeons. Here's why.

UNI-SHUNT*—the unique one piece shunt.
Simple and easy to insert, it's one piece construction reduces the risk of infection and need for revision.

ACCU-FLO*—the guaranteed system which offers complete flexibility.
The Accu-Flo range of shunts offer the surgeon a complete system from which to choose. They are also guaranteed to function at the stated pressure. Renowned for their consistently high quality and low cost—up to 20% less than some competitive products—Accu-Flo shunts are also double sterile wrapped.
The whole range is available from stock, so there's no delay when ordering. For more details, fill in the coupon.

Genetic registers

Two-thirds of couples referred for genetic advice after the birth of an affected child were deterred from having further children when given high recurrence risks (greater than 1 in 10, and usually 1 in 2 or 1 in 4).[1] Thus in a sense, genetic counselling can prevent genetic disease by birth control; but there are also more opportunities for prenatal diagnosis and selective abortion, which can lead to compensatory birth of unaffected children. About 85% of relatives deemed to be at high risk of having a child with a serious genetic disorder have never been given counselling and are unaware of the risks,[2] and therefore genetic registers designed to improve ascertainment and follow-up of these individuals so that they may be offered genetic counselling, seem a reasonable idea.

In 1977 the Committee of the Clinical Genetics Society formed a Working Party in order specifically to consider: the nature of genetic registers, their value and potential application particularly with regard to the prevention of genetic disease; the place of registers for specific genetic disorders—such as Huntington's chorea—and genetic disorders in general where relatives may be at high risk; and the feasibility and acceptability of genetic register systems organised either nationally or locally. The chairman, Professor A. E. H. Emery, has just produced his report.[3]

Existing registers

At present 38 centres in Britain maintain registers primarily concerned with genetic disease so, in practice, the Working Party considered the direction in which we should go rather than whether or not we have genetic registers at all. Existing registers were designed with different functions in mind, and range from not much more than a simple refinement of normal medical records to what the Working Party calls preventive registers designed to improve the ascertainment and follow-up of individuals at risk of transmitting a serious genetic disorder to their offspring, so that they may be offered genetic counselling, including prenatal diagnosis if possible.

It is preventive registers and, to some extent, the large reference research registers that will have far reaching implications for the public and the medical profession. The report outlines three existing computer-aided registers as examples. The RAPID (Register for the Ascertainment and Prevention of Inherited Disease) system was first established in Edinburgh in 1970 and much of what is recommended by the Working Party seems based on this system. The Indiana MEGADAT (Medical Genetics Acquisition and Data Transmission) system collects and processes information on families with genetic disorders at the rate of 1500 per year, and by 1975 had already incorporated data on one-third of a million individuals. The Belgian National Register contains data on all persons (about 6000 a year) referred to any of the seven Belgian medical genetic centres. The last two are very large, multipurpose registers not planned or recommended for this country, and so debate will centre on the recommendations for preventive registers.

Approaching relatives

A particular problem with the establishment and use of genetic registers (dealing largely with dominant and X-linked recessive diseases) is that diagnosis of the disorder immediately generates important information on relatives who themselves have not sought medical advice. This creates the problem of how to approach family members. The index case has the right to refuse disclosure of his diagnosis to his relatives. Indeed a proportion will express this desire, but in his initial request the doctor may have already intimated that withholding permission to approach relatives could mean unnecessary suffering in the family. The patient now has this extra burden of responsibility to add to his problems. In their discussion of this and similar issues, the Working Party rightly concentrates on the role of the family doctor, so that relatives at high risk are contacted only with the express permission of both the index case and the relative's family doctor, through whom it is best to establish contact. Paediatricians and other specialists will also undoubtedly become involved, and if the activities related to the register are seen to be clearly within the general bounds of family health care, then the majority of families are likely to welcome both the approach and the subsequent counselling. I think it was this sort of sentiment that made the Working Party favour a regional rather than a national register. Access to information in the register can, with care, be regulated and limited appropriately; what is much more difficult is to safeguard the interests of those families whose beliefs differ from 'popular' opinion. I believe the tide of prenatal diagnosis is already claiming a few who would have liked to have thought about it longer.

Recommendations of the Clinical Genetics Society Working Party

The Working Party make the following recommendations:

(1) Registers should be set up for the express purpose of tracing, following-up, and counselling individuals who are at high risk (greater than 1 in 10) of transmitting a serious genetic disorder to their offspring. The object is to ensure that such individuals are informed of the risks and the various options available to them.

(2) Registers should be organised on a 'regional' rather than a national basis, and should be located in a regional genetics centre. If registers already exist in units dealing with specific genetic disorders—such as haemophilia—there should be close liaison with the regional genetics centre in order to provide comprehensive facilities for counselling, including risk estimation.

(3) No individuals should be included on the register without their knowledge and approval.

(4) The involvement of family doctors should be sought in every case and encouraged at all stages of contacting, counselling, and follow-up of individuals at risk.

(5) The complexity of the data and the need for co-operation between centres requires a standard form for recording data and an agreed system for coding disease entities. This system should accommodate chromosomal, multifactorial, and unifactorial disorders and should be sufficiently flexible to include newly recognised genetic disorders and possible heterogeneity.

(6) Computerisation of data in a genetic register is recommended for several reasons. It becomes important for ease of storage and retrieval of data (including patient recall) if large numbers are involved. It has the advantage that, with appropriate safeguards, it helps to maintain strict confidentiality. It also provides a facility for fulfilling other functions such as complex risk calculations.

(7) The computer system for a genetic register should ideally have a dedicated minicomputer located in the genetic centre. The main advantages are increased confidentiality and facility of operation. A less satisfactory alternative is a terminal associated with a large central computer.

(8) There should be standardisation of computer equipment and computer programs, both for economic reasons and to facilitate collaboration between different genetic centres. Therefore, it is essential to co-ordinate developments in this field.

(9) The computer program, like all other aspects of the genetic register system, must incorporate strict safeguards for confidentiality.

(10) Access to data in the register must be restricted to certain clearly specified individuals. Personal and medical information should be released only by the clinician in charge of the register.

(11) In establishing a 'regional' genetic register, provision must be made for adequate supporting staff, which might reasonably include a medical geneticist, a clerk/computer operator, and a field worker.

(12) If a general genetic register is not immediately feasible for economic or other reasons, a limited register should be established for specific genetic disorders of particular importance.

It is desirable that there should be as wide a debate as possible both in and outside the profession before these recommendations are implemented in full. Who is going to monitor the success or failure of this important venture?

Results of a regional cord blood screening programme for detecting neonatal hypothyroidism

PAUL G. WALFISH, JODY GINSBERG, R. ARLEN ROSENBERG, AND
NEVILLE J. HOWARD

Mount Sinai Hospital, University of Toronto, and Hospital for Sick Children, Toronto, Canada

SUMMARY Our regional cord blood screening programme for detecting neonatal hypothyroidism using initial cord blood thyroxine (T4) determinations, with supplemental thyrotropin (TSH), and triiodothyronine resin uptake (T3U) measurements, gave an incidence of thyroid abnormalities of 1/3000 births, with 1/5000 infants having severe primary hypothyroidism. No hypothyroid infant detected in the programme had been suspected clinically before the screening and, in retrospect, only a few babies had any signs of hypothyroidism. Supplemental TSH and T3U determinations were required on 8–12% of the population screened initially with a T4 test to avoid missing affected cases. With an initial T4 and supplementary TSH and T3U testing on cord blood serum, recalls to exclude primary hypothyroidism were reduced to 0·16% of the screened population. The incidence of abnormalities detected in this cord blood screening programme was comparable with that reported by others using neonatal dried blood screening methods, indicating that cord blood screening can be effective provided the appropriate recall criteria and transport conditions are used. Nevertheless, for several practical reasons, neonatal dried blood methods are recommended as the screening test of choice for surveying large populations over extensive geographical areas.

Neonatal hypothyroidism is a condition that may result in mental retardation. Retrospective studies show that treatment before age 3 months lessens the chance of this outcome (Raiti and Newns, 1971; Klein *et al.*, 1972). As it is difficult to make an early clinical diagnosis, laboratory screening programmes have been implemented (Fisher *et al.*, 1976). Cord blood serum TSH alone (Klein *et al.*, 1974), or thyroxine combined with thyrotropin (TSH) (Walfish, 1976), have been used. Alternatively, dried blood spotted on filter paper discs after heel prick at age 3–5 days has been used to measure T4 alone (Dussault *et al.*, 1976), TSH alone (Irie *et al.*, 1975; Illig and Rodriguez deVera Roda, 1976; Larsen *et al.*, 1976; Miyai *et al.*, 1976; Foley *et al.*, 1977), or initial T4 with supplementary TSH (Scriver *et al.*, 1977; Dussault *et al.*, 1978). Neonatal heel prick capillary serum TSH has also been assessed as a screening test (Delange *et al.*, 1977).

To detect neonatal hypothyroidism and lessen the burden of recall in a screening programme using T4 alone (Walfish, 1976), our programme used an initial cord blood serum T4, with selective supplemental TSH and triiodothyronine uptake assays (T3U) to obtain epidemiological data on this disorder in Toronto. The purpose of this report is to summarise the laboratory and clinical data for the 16 infants with confirmed thyroid dysfunction among the 50 000 infants who were tested in this large-scale regional screening programme.

Materials and methods

Cord blood sera and venous samples from patients who were followed up were obtained in a regional screening programme to detect neonatal hypothyroidism. The programme was started in October 1973 at the Mount Sinai Hospital, Toronto, and this was extended to other Toronto Hospitals with approval of the University of Toronto Committee on Human Experimentation.

Cord blood was obtained after delivery and ligation of the umbilical cord by withdrawing with a syringe 3 to 5 ml venous blood from the placental side. This was stored and taken at 4°C to a central laboratory. After being separated by centrifugation, sera were stored at −20°C until analysis. All assays were performed in duplicate. Using 25 μl serum samples, cord T4 was measured in all infants by a double antibody radioimmunoassay (RIA) technique (Chopra, 1972; Walfish *et al.*, 1973). Each assay 'run', comprising 200–700 samples, was analysed by a histogram and those infants with low T4 values up to either the 8th or 12th centile, depending on the distribution of values, had supplemental duplicate 100 μl serum TSH determinations, using a double antibody RIA (Patel *et al.*, 1971) and duplicate 100 μl serum T3 uptakes with silica talc resin (normal cord serum T3U range relative to pooled control reference was 78 to 110%). Infants in whom the TSH value was >45 μU/ml were followed-up as quickly as possible with additional venous T4, TSH, T3U and, in some cases, total serum triiodothyronine (T3) by RIA (Chopra *et al.*, 1972).

If a persistent abnormality of the thyroid function was noted, the infant was investigated further at the Hospital for Sick Children, Toronto; investigations included repeat serum thyroid function studies, a low dose radioiodine uptake, a technetium thyroid scan, and bone age studies (Greulich and Pyle, 1959).

A low dose (1–2 μCi)^{131}-I uptake was obtained at 2 and 24 hours. This was followed by a technetium 99M rectilinear scan using a 0·5–2 mCi IV dose according to body surface area.

Table 1 gives the nomenclature used.

Results

Thyroid indices on cord blood and at the time of follow-up for the 16 hypothyroid infants are shown in Table 2, including the in-assay location of the cord blood thyroxine value. A summary of the results according to underlying aetiology is shown in Table 3.

The cord blood serum T4 levels in the 16 hypothyroid infants ranged from 2·9 to 8·1 μg/100 ml

(37 to 104 nmol/l), Table 2. The mean ± SD was 5·5 ± 1·7 μg/100 ml (71 ± 22 nmol/l). This was significantly lower by Student's *t* test ($P<0\cdot001$) than the mean T4 of 10·7 μg/100 ml (138 nmol/l) for 4911 normal euthyroid infants previously reported (Walfish, 1976). Eight of the 16 hypothyroid infants had T4 levels within 2 SDs of the normal mean (Table 2). When only those infants with severe primary hypothyroidism (Table 1) are studied, the mean T4 is 4·9 ± 1·6 μg/100 ml (63 ± 21 nmol/l) which is not significantly different from the mean for all the hypothyroid infants. However, those without severe primary hypothyroidism have a mean T4 of 6·7 ± 1·6 μg/100 ml (86 ± 21 nmol/l), significantly higher ($P<0\cdot05$) than for other hypothyroid infants. At follow-up the level of T4 had decreased in all except the 2 infants with hypoplasia.

All infants with primary hypothyroidism had cord TSH >45 μU/ml. Those infants with severe primary hypothyroidism had TSH >100 μU/ml. In all cases (except for the child with secondary hypothyroidism), TSH levels remained >40 μU/ml at the time of the 3–5 week follow-up, when the normal TSH level is less than 10 μU/ml.

Total serum T3 (RIA) was obtained in 11 hypothyroid infants at the time of follow-up and ranged from 30–225 ng/100 ml (0·5–3·4 nmol/l). T3 (RIA) was subnormal (compared with normal adult values) in only 4 of the affected infants and was not a good indicator of hypothyroidism. 14 hypothyroid infants had T3U performed and, in all except one, T3U was within normal limits. Values tended to be parallel to the T4 values, but no infant had a T3U suggestive of primary thyroxine-binding globulin abnormality.

149 (0·3% of the total population) infants have been recalled for suspect primary hypothyroidism. When the number of affected infants is subtracted from the total number recalled and expressed as a percentage, 90% of the recalled infants were proved to be euthyroid at follow-up. 51 infants with T4 in the lowest 12th centile and T3 uptakes >120% were not recalled for suspect hypothyroidism but were followed up, and 8 were shown to have a persistent TBG abnormality. The estimated incidence for our population is therefore 1/6500, which is greater than the incidence previously reported (Dussault *et al.*, 1977) in which direct measurements of TBG were used.

As the TSH assay used in this programme was no more sensitive at its lower limits than 6 μU/ml, it mainly helped to detect primary hypothyroidism. Case 16 was discovered fortuitously to have secondary hypothyroidism, as he was recalled in the early stages of our programme when all infants with low T4 levels were followed up. More recently, those patients with cord serum T4 values in the lowest 12th centile with values below the lower limits of detectability on the supplementary TSH test have not been recalled, and this has reduced the percentage recalled for primary hypothyroidism to 0·16% by excluding follow-up of low T4 infants with low TSH (i.e. possible hypo-TBG-aemia or secondary hypothyroidism).

Clinical studies

Salient data for the 16 infants with thyroid function abnormalities are summarised in Table 4. The babies (9 boys and 7 girls) ranged in gestation from 34 to 42 weeks. Only one (Case 13) had an abnormal birthweight, being low for gestational age. This child had the additional problems of hypospadias, hypoglycaemia, and hypocalcaemia. Follow-up examination was generally between the 14th and 39th day. However, 2 babies in the series were seen later—Case 1 at 80 days, because of a change in her address, and Case 16, who has hypopituitarism, at 308 days, due to reluctance in referral by his doctor. No hypothyroid infant discovered in the screening programme had earlier been suspected to have

clinical hypothyroidism. At the initial examination all babies were assessed for hypothyroidism using the criteria of Smith *et al.* (1975). Seven out of 16 had at least one of these criteria; the remaining ones were clinically euthyroid. Three babies had enlarged thyroids, 2 of whom were in the overtly hypothyroid group. The heights and weights of the study group were in the normal range with the exception of 4 premature infants and Case 13. Several babies (Cases 3, 5, 7, 14, and 16) were overweight for their length but only 2 of them were clinically hypothyroid.

Radiological bone age, estimated by the method of Greulich and Pyle (1959), and compared with the age at assessment, was abnormal in 8 of the babies whereas the 24-hour radioiodine uptake was abnormal in all 15. 11 babies had a low uptake, while 3 of the 4 babies with enzyme defects, and the infant with iodine-induced goitre, had increased uptake. Technetium scan detected hypoplastic lingual thyroids in 3 (Cases 9, 10, and 11) and suggested athyrosis in 4 others. The diagnoses made are given in Table 3. 11 infants had significant primary hypothyroidism requiring thyroid replacement with L-thyroxine 5·0–7·5 μg/kg (64–96 nmol/kg) a day. Treatment was started in this group between 15 and 80 days, with a mean starting day of 32, and more recently of 22 days. Case 15, with iodide-induced hypothyroidism, was initially treated with L-thyroxine but his treatment was stopped at age 2 months when the cause was established and he remained euthyroid at subsequent follow-ups. The 3 infants with hypoplasia had subclinical hypothyroidism at reassessment; and 2 were treated with thyroxine replacement but one of these, Case 12, died from sepsis and at necropsy his thyroid gland was shown to be hypoplastic. The family of the one remaining baby in this group, Case 14, elected not to allow treatment, and at age 12 months he was physically and developmentally normal but he still had a raised TSH with normal T4 and T3 levels. Case 16 with hypopituitarism, has hypogonadotropic hypogonadism, and hypothyroidism associated with congenital microcephaly, and moderately severe developmental delay. Thyroid replacement in this child improved his height velocity.

Discussion

This cord blood programme using initial T4 screening with supplemental TSH determination gave a yield of thyroid abnormalities of 1/3000 births with a 1/5000 incidence of severe primary hypothyroidism. This correlates well with the findings of other screening programmes using either cord blood or dried blood spots (Fisher *et al.*, 1976). This is a much greater incidence than that for phenylketonuria (1/16 000) for which screening programmes already exist, and much greater than 1/20 000 estimated from retrospective examination of hospital admissions for cretinism in Toronto (unpublished data). The discrepancy may be caused by early detection of cases that would not have presented with cretinism. However, those cases without athyrosis (i.e. enzyme defect, lingual thyroid, etc.), although biochemically hypothyroid, may in fact not have developed clinical hypothyroidism until later. The particular significance of the 3 cases of hypoplasia is not clear. Such cases may represent either subclinical hypothyroidism or a form of pituitary resistance syndrome where there is a raised serum TSH in the presence of a normal to raised serum T4 concentration (Gershengorn and Weintraub, 1975).

Our programme requires supplementary TSH estimations on the lower 8–12th centile of the T4 'run'. This high incidence of supplemental TSH determination using cord blood serum is necessary because T4 levels may be low in premature infants, twins, and in other euthyroid infants (Walfish, 1976; Ginsberg *et al.*, 1978). The technical and clinical problems that could arise from using an absolute value of T4 for determining which samples have supplemental TSH testing within a screening programme has previously been discussed (Walfish, 1976). As the cord serum T4 was within the 95th centile of the normal population for most of the affected hypothyroid infants, we feel it is necessary to take a relatively large number of infant samples for supplemental TSH estimations to avoid the possibility of missing a hypothyroid infant. Similarly, a hypothyroid infant with cord serum T4 values above the lower 2·5th centile of the normal general population has been reported (Klein *et al.*, 1976). Because of its relative nonspecificity and the high recall burden imposed by screening for T4 alone, it is not recommended as the only screening technique (Walfish, 1976; Scriver *et al.*, 1977; Dussault, *et al.* 1978).

Several high false-positive TSH values were seen secondary to extreme parturition stress (Walfish, 1976; Delange *et al.*, 1977). No false-negative results have so far been seen as all infants with primary hypothyroidism had TSH values >45 μU/ml, and those with very significant primary hypothyroidism had values >100 μU/ml. As stated earlier, TSH is the single most specific test for detecting infants with primary hypothyroidism. Because of the cost of reagents and the need for technical expertise (and the inability to detect secondary hypothyroidism or TBG abnormalities), we have not advocated a TSH test as the only screening method. However, if one wanted to rely on a single test to detect primary hypothyroidism, TSH screening would seem to be the most appropriate. So far our programme, using an initial T4 with a supplementary TSH and T3U test on cord blood serum, has decreased the number of patients needed to be followed up for primary neonatal hypothyroidism to an acceptable 0·16% of the total population. If a cord blood sample is not received, then a dried blood heel prick spot is obtained at between 3 and 5 days and initial T4 and supplementary TSH tests performed. To our knowledge, no infant with primary hypothyroidism has failed to be detected (i.e. no false-negative results).

The clinical and laboratory data recorded here are somewhat at variance with those in current texts. Rather than showing a female preponderance (Carr *et al.*, 1961; Andersen, 1969), the sex ratio is equal, but the small number of subjects may be the reason for this. Fewer than half of the cases showed any criterion of hypothyroidism using the parameters of Smith (Smith *et al.*, 1975). This finding is in direct contrast to that of Guyda *et al.* (1977), but it is in agreement with the data of others; Klein *et al.* (1976) found little clinical evidence of hypothyroidism among their detected infants. In contrast to other reports (Smith *et al.*, 1957, 1975), delayed radiological bone age, as an index of skeletal maturation, did not correlate well with hypothyroidism in our series.

While awaiting the results of the hormone assay, a low dose 24-hour radioiodine thyroid uptake was performed and, if this was abnormal, replacement therapy could be begun. Technetium scanning allowed the defect in the thyroid to be estimated so that appropriate genetic counselling could be given to the parents. A low dose ^{131}-I uptake procedure was routinely performed but the technetium 99M scan could be used instead for the anatomical localisation of the thyroid gland abnormality with less radiation exposure. Nevertheless, information on goitrous lesions and their underlying biosynthetic defects can be obtained from radioiodine studies (^{123}-I preferably if available) at negligible radiation risk if the appropriate low doses are used.

The distribution of diagnoses in this small number of cases differs from that in previous reports in which it is suggested that most cretins have athyrosis (Wilkins, 1960; Carr *et al.*, 1961). In our group only 30% were athyrotic, 30% had enzyme defects, and 20% lingual glands. This distribution is similar to that found by others (Andersen, 1966) from an analysis of congenital hypothyroidism based on radioiodine thyroid uptake.

Cord blood serum is easy to obtained, it can be handled easily, and it requires less cumbersome radioimmunoassay procedures for T4 and TSH than the dried blood spot. Excess serum is also readily available for repeat analyses and for T3U tests for determining abnormal thyroid hormone protein binding. The main difficulty with such a method is that the sample has to be sent to a central laboratory and then isolated from other inborn error screening tests. Dried blood placed on filter paper is an alternative method and has the advantage that it can be transported over wide areas (Fisher *et al.*, 1976; Scriver, 1977; Dussault *et al.*, 1978). Such a technique may be combined with screening for phenylketonuria and with other inborn error screening programmes that can be assayed from neonatal dried blood filter paper discs (Scriver *et al.*, 1977). However, assays performed from dried blood filter paper discs require proper collection and saturation of both surfaces of the filter paper (Walfish, 1975), and there is the risk of blood TSH instability and a significant reduction in measurable TSH activity within several weeks at high ambient temperatures (Naruse, 1978; P. G. Walfish, 1979, in preparation) such as may occur if they are sent by post. The estimated cost for the cord blood screening programmes as described, using initial cord blood serum T4 determinations with supplementary TSH and T3U assays is $1.50 per infant excluding overhead and capital equipment expenditures, but other dried blood programmes have reported similar or lower costs (Fisher *et al.*, 1976).

Regardless of whether cord blood serum or neonatal dried blood is used, screening programmes for neonatal hypothyroidism will find it difficult to detect infants with secondary hypothyroidism (low T4 with low TSH) who reportedly represent between 6 and 10% of the total neonatal hypothyroid population (Fisher *et al.*, 1976; Dussault *et al.*, 1978). However, the low incidence of secondary hypothyroidism, its difficulty of detection, and the overlap with normal infants having low TSH values will require an unusually high burden of recall of over 1% of the population surveyed (Dussault *et al.*, 1978) in order to detect such cases; this is a known limitation of any screening programme regardless of method, owing to the poor discrimination between infants with low TSH secondary hypothyroidism, those with low TSH of congenital hypo-TBG, and normal infants. Our programme has therefore recently been altered to screen only for primary neonatal hypothyroidism and this has further reduced the number recalled to 0·16%.

Despite these limitations, the high incidence of thyroid abnormalities detected by cord blood screening has shown that this approach may be as effective as neonatal dried blood screening methods in detecting neonatal hypothyroidism if the appropriate recall criteria and transport conditions are used. This study shows that cord blood serum screening was successful in detecting neonatal hypothyroidism within densely concentrated population areas with high birth rates, provided that a central assay laboratory is available to optimise quality control and to reduce administrative costs. Nevertheless, owing to the practical considerations, and in agreement with previous reports (Fisher *et al.*, 1976; Scriver *et al.*, 1977), we recommend the neonatal dried blood collection method as the screening test of choice when surveying large populations over extensive geographical regions.

Although supported by retrospective studies (Raiti and Newns, 1971; Klein *et al.*, 1972), the value of prompt detection and early thyroxine replacement remains to be assessed prospectively, in our cases of primary hypothyroidism. It is too soon to assess accurately the intellectual development for these infants, but at present all primary cases appear to be growing at a normal velocity and have normal motor milestones, suggesting that early detection and therapy have been of significant value.

We appreciate the technical assistance of Mrs E. Gera, Mrs M. Grant, Mrs A. Bansil, Dr R. Talosig, Mrs M. Weiner; the nursing assistance of Mrs C. Schonberg, the secretarial assistance of Miss S. Windatt; the US National Institutes of Health, (National Institute of Arthritis, Digestive and Metabolic Diseases) Pituitary Agency, the WHO and Division of Biological Standards, Holly Hill, UK for TSH and their supplies, and the volunteer assistance for the refrigerated cord blood pick-up and transport of the Toronto Chapter of the Canadian Red Cross; the obstetric and paediatric staff of all participating hospitals; and the assistance of Dr J. Bailey of the Hospital for Sick Children, Endocrine Service, Toronto.

Response of term babies to a warm environment

N. RUTTER AND D. HULL

University Hospital and Medical School, Nottingham

SUMMARY The response of healthy term babies to warm environments was assessed by placing them naked in incubators and increasing the air temperature in steps until either sweating occurred or the rectal temperature reached 37·9°C. The rate of evaporation of water from the skin was measured by a method based on the estimation of vapour pressure gradient. When a 50% increase in the rate occurred at a given site, sweating was judged to have begun. 39 studies were made on 30 babies, aged from 4 hours to 11 days. As babies approached the point of sweating, spontaneous activity usually ceased, the skin reddened, and a sunbathing posture was adopted. Sweating was found on 35 occasions. It was most pronounced and often was found initially on the forehead but it was also detected on the trunk and limbs. No thermal sweating was noted on the palms or soles. Sweating generally began when the incubator air temperature exceeded 34°C and the rectal temperature exceeded 37·1°C, but there was wide individual variation. Older and more mature babies tended to sweat at lower air temperatures.

Sweating is man's most important defence against overheating. It is highly developed in the heat-acclimatised adult who can lose over a litre of water an hour by this route, an evaporative heat loss of 700 W. Before sweating occurs, skin blood flow is increased which raises skin temperature and increases heat loss by radiation and convection. By these adjustments adults are able to maintain deep body temperatures within a narrow range in high environmental temperatures. Very few investigations have been made on the response of the newborn baby to high ambient temperatures. By virtue of his size the newborn in the company of adults is more at risk of cold exposure. However, the clinical emphasis on the importance of keeping babies warm has led to the introduction of powerful heating devices, such as incubators and radiant warmers, into routine service and with this has come the risk of overheating. Just as it is important to know the ambient temperatures at which babies of different ages, sizes, and gestations switch on thermogenesis thus increasing their need for oxygen and substrate, so it is important to know the ambient temperatures at which they are likely to begin to sweat and thus increase their need for water.

A simple method for measuring evaporative water loss from the skin is available (Nilsson, 1977). We used this in combination with measurements of skin temperature to study the range of responses of the healthy term baby to high environmental temperatures.

Method

Rates of evaporation of water from the skin were measured with the Evaporimeter EP1 (Servomed), a method based on estimation of the water vapour pressure gradient close to the skin's surface. The technical details have been reported by Nilsson (1977).

Each baby after a feed was placed naked on his back inside an incubator (Vickers 79). The air temperature of the incubator was set near the lower point of the thermoneutral range according to the values reported by Hey (1971). The probe of the Evaporimeter was placed lightly on the baby's skin until a stable reading of evaporation rate was obtained. Measurements were made at 11 defined skin sites on each baby: forehead, cheek, chest, abdomen, anterior upper arm and forearm, palm, anterior thigh and lower leg, dorsum of the foot and sole. These sites were chosen so that the infant lying on his back was not disturbed. At the same

time, the following temperatures were measured by thermocouple: air temperature in the centre of the incubator, skin temperature of the upper abdomen and dorsum of the hand by lightly taping the thermocouple to the skin, and rectal temperature, with a probe inserted about 8 cm into the baby's rectum.

30 minutes were allowed for the infant to adjust to any change in environmental conditions. After the initial readings were made, the incubator air temperature was increased in steps of 0·5–1·5°C. 30 minutes later, evaporation rates and temperatures were recorded before the incubator air temperature was again increased, and this sequence was continued until the baby began to sweat or until his rectal temperature reached 37·9°C. This is the average body temperature of babies before birth (Mann, 1968). As sweating is influenced by exercise as well as by temperature, measurements were not made on active or crying babies. In this study sweating was defined as an increase in evaporation rate of at least 50% above the initial rate of water loss from that skin site. In most cases the increase was considerably greater, in some instances 10 to 18 times higher than the initial values. The upper critical temperature of the thermoneutral range is usually defined as that environmental temperature at which sweating first occurs. As the incubator air temperature was increased in steps, the upper critical temperature for each baby was somewhere between the air temperature at which sweating did not occur and the air temperature at which it did. Because this point was not accurately defined, we have expressed all our results in terms of the incubator air temperature at which sweating was first detected. This temperature is not the operative environmental temperature because no allowances were made for radiant heat exchange between the baby and the inner surface of the single-walled incubator. The average room temperature was 27·2°C (range 24·9–29·9°C). Thus the operative environmental temperature was likely to be about 1°C lower than the actual incubator air temperature (Hey and Mount, 1966). The relative humidity inside the incubator was not controlled but it was measured. It varied between 26 and 58%.

39 studies were made on 32 healthy term babies. Gestational age was calculated in completed weeks of pregnancy from the first day of the mother's last menstrual period. It ranged from 37 to 42 weeks (mean 39·7). Birthweight ranged from 2·77 to 4·70 kg (mean 3·43). The age of the baby varied from 4 hours to 11 days. Each study was made with the full informed consent of the mother, usually in her presence, and the investigation was approved by the North Nottinghamshire Health District Ethical Committee.

Results

The results of a typical series of observations are illustrated in Fig. 1. With each increment in incubator air temperature, the peripheral temperature on the dorsum of the hand rose sharply. Abdominal skin and rectal temperatures also rose, but at a slower rate. After 30 min at an incubator air temperature of 36·6°C, when the peripheral and abdominal skin temperatures were the same and the difference between skin and rectal temperature was only 0·5°C, the baby began to sweat.

The incubator temperatures were never raised so that the infant's rectal temperature exceeded 37·9°C. With this limitation, sweating was detected in 35 out of the 39 studies. On 11 occasions sweating was only noted on the forehead. On 14 occasions it occurred on the forehead first and only appeared elsewhere when the air temperature was further raised. It then progressed to the chest, arms, abdomen, and legs, usually in that sequence. On the remaining 10 occasions, sweating was noted at several sites simultaneously, always including the forehead. The mean rates of evaporation of water at the different sites, initially and after sweating occurred, are shown in the Table. Sweating was most pronounced on the forehead.

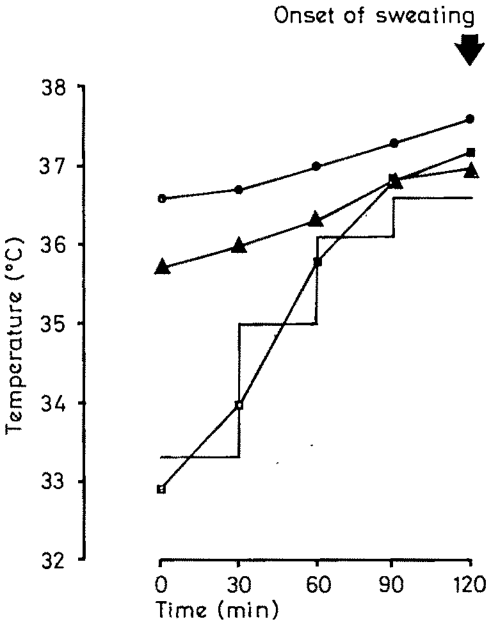

Fig. 1 *The effect of step-wise increases in the incubator temperature (——) on body temperatures (● rectal, ▲ abdominal skin, ■ hand) of a naked, term infant, birthweight 2·95 kg, age 21 hours. The arrow head indicates when sweating began.*

Table *Mean rates of evaporation from different skin sites in 39 babies. Initial rates were obtained after the baby had been naked in an incubator for 30 min at a temperature near the lower end of the thermoneutral range. Sweating was judged to have occurred when, after increasing the ambient temperature, the evaporation rate increased by at least 50% above the initial value*

Skin site	*Mean initial evaporation rate (g/m² per hour)*	*Mean maximum evaporation rate when sweating (g/m² per hour)*	*No. of times sweating detected (no. of studies = 39)*
Forehead	6·2	52·6	35
Cheek	8·2	16·2	13
Chest	4·8	16·7	21
Abdomen	4·9	11·3	15
Upper arm	5·6	12·5	14
Forearm	5·2	15·3	18
Palm	14·6	—	0
Thigh	5·4	12·3	11
Lower leg	4·9	11·8	12
Foot—dorsum	4·6	13·2	7
Foot—sole	9·6	—	0

There were wide variations in the incubator air temperatures, the rectal temperatures, and the abdominal skin temperatures at which sweating was first detected (Fig. 2). There was a significant trend for infants of longer gestations to sweat at lower ambient temperatures but there was no obvious difference in the skin and rectal temperatures at which sweating first occurred in the more mature babies (Fig. 3). Infants who were at least 6 days old, sweated at significantly lower ambient temperatures than infants in the first 4 days of life, but again no change in the skin and rectal temperatures when sweating occurred was noted as the postnatal age increased (Fig. 4). Four infants were studied serially during the first week of life. In all 4 the air temperature at which sweating was first observed fell by 1·3–2·6°C. The relative humidity of the incubator air, in the range of 26–58%, did not appear to influence the ambient temperature at which sweating first occurred.

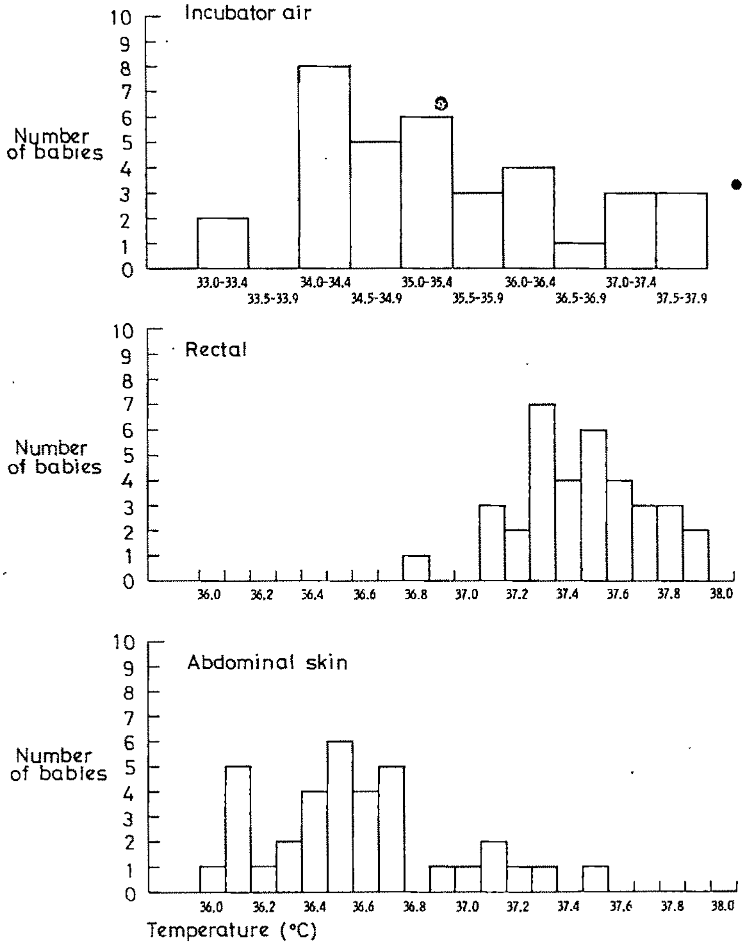

Fig. 2 *Temperatures of the incubator air, rectum, and abdominal skin at which sweating was first detected in 35 infants.*

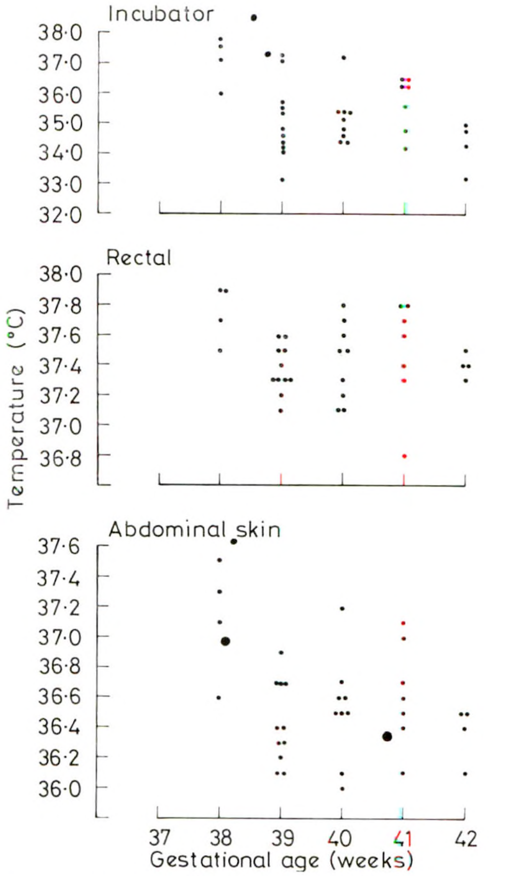

Fig. 3 *Relationship between gestational age and the incubator air, rectal, and abdominal skin temperatures at which sweating first occurred. The more mature infants began to sweat at lower incubator air temperatures* (*P* = *0·05*).

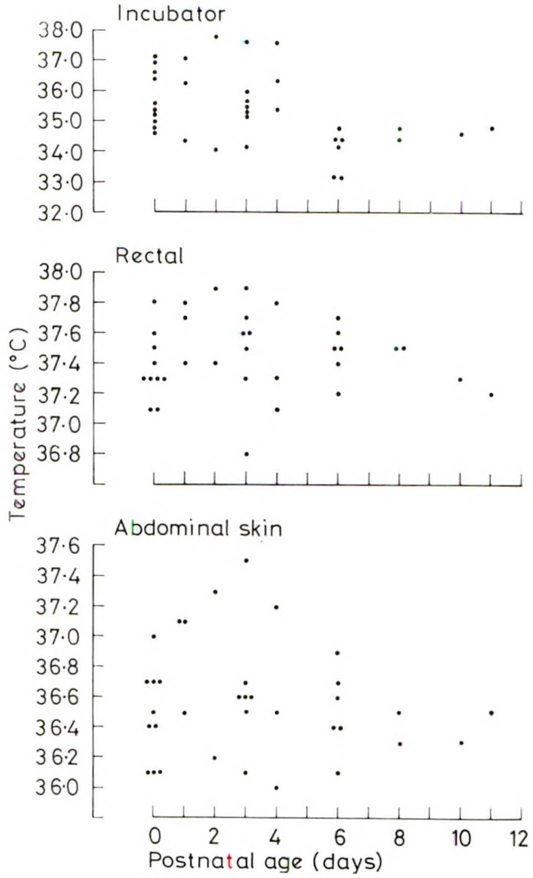

Fig. 4 *Relationship between postnatal age and the incubator air, rectal, and abdominal skin temperatures at which sweating first occurred. Babies aged 6 days or more, sweat at significantly lower air temperatures than those aged 4 days or less* (*P* = *0·01*).

In the infants who did sweat, sweating occurred when the peripheral and abdominal skin temperatures were similar and the rectal and skin temperatures differed by about 0·5°C. In the 4 infants who did not sweat, these conditions were reached and all the measured temperatures then rose with each upward step in ambient temperature without detectable sweating (Fig. 5).

In a few instances, sweat was visible on the forehead when rates of sweating were very high but usually it was not seen. Certainly the onset of sweating could not be detected visually. However, the infants did make consistent responses to the increasing ambient temperature. As the air temperature rose the skin colour reddened, spontaneous movements diminished, and when sweating began the infants assumed the posture of a sunbathing adult, lying supine with arms and legs outstretched (Fig. 6). No panting was observed.

Discussion

Sweat response. We have demonstrated that term babies are able to sweat and that sweating readily occurs on the first day of life. This was not found by Uchino (cited by Kuno, 1956) who measured water loss from the chest only, but it was reported by Hey and Katz (1969) who measured total evaporative water loss in a metabolic chamber. We cannot explain why 4 babies did not sweat in spite of high rectal temperatures, although 2 were shown on a later occasion to be able to do so. We found that

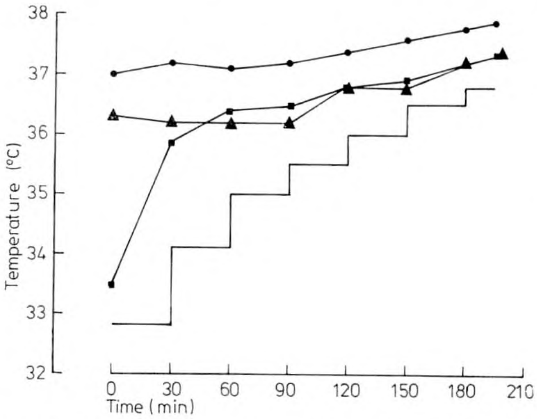

Fig. 5 *The effect of step-wise increases in the incubator temperature (——) on body temperatures (● rectal, ▲ abdominal skin, ■ hand) of a baby in whom no sweating was detected. The baby was born at 37 weeks' gestation, weighing 3·41 kg, and was 6 days old when studied.*

the forehead was the earliest site at which sweating occurred, that it was usually most intense there, and that it was sometimes the only site where a sweat response was detected. We chose the centre of the forehead because it was a convenient site for measurement but sweating of similar intensity was found simultaneously on the temples, behind the ears, and over the occiput but sparing the top of the scalp. Sweating on the forehead of the newborn infant was observed by Foster *et al.* (1969); they pointed out that the sweat glands at this site are the first to develop in fetal life. When progression of sweating occurred, the order from head to chest, arms, abdomen, and legs was similar to that described in adults (Rothman, 1954). Furthermore the relative intensity of sweating at the different sites is similar to adults (Kuno, 1934), but absolute values are generally lower. It must be pointed out however, that we did not attempt to press the infants to their maximum possible rates of sweating. Hey and Katz (1969) found that evaporative water loss per unit area is lower in the sweating baby than the sweating adult. The high initial rates of water loss from the palms and soles which did not change as ambient temperature increased were noted in adults by Kuno (1934). Perpetual sweating is thought to occur at these sites and cannot be abolished by cooling; described as emotional or mental sweating, it can be induced in an adult by mental arithmetic or anxiety.

Both gestational age and postnatal age influenced the environmental temperature at which sweating occurred but there was much individual variation. Many factors are likely to be involved, including maturation of control systems, variations in thermal insulation, and differences in resting metabolic rates. The charts of Hey (1971) suggest that term babies nursed naked in incubators do not greatly increase their evaporative water loss until the operative environmental temperature reaches about 34°C on the first day or 33°C at about 10 days of age. Our results are generally consistent with these observations, as only a few babies sweated at temperatures below these and most babies did so at temperatures 0·5–1·0°C higher. The fall in incubator air temperature at which sweating first occurred as postnatal age increased was independent of gestational age. It mirrors the rise in resting metabolic rate which

Medulloblastoma—a changing prognosis?

NEIL McINTOSH

University College Hospital, London

SUMMARY 87 of 90 consecutive cases of medulloblastoma diagnosed at The Hospital for Sick Children, London, in the 10-year period 1965–74 were followed-up until death or until 1 January 1978. Only one patient survived in the 1st 5-year period and is a cure. In the 2nd 5-year period 17 (41 %) of 41 patients presenting are alive and, of these, 11 are 5-year survivors (= 39 % of possible 5-year survivors). Reasons for this improvement are discussed; it is thought likely that the main contribution is improved radiotherapeutic techniques.

Since Bailey and Cushing established medulloblastoma as an entity in 1925, it has been regarded as a predominantly paediatric cerebral tumour with a poor prognosis. Cushing (1930) showed that survival with radical surgery alone was impossible so that the current mainstays of treatment are a combination of surgery and radiotherapy. Surgery to the posterior fossa is as radical as is allowed at operation, and is followed by radiotherapy to the whole craniospinal axis as seeding occurs through cerebrospinal fluid paths. Until the 1950s very poor survival rates were uniformly reported (e.g. Lampe and MacIntyre, 1949; Chatty and Earle, 1971), but since then prognosis has improved, almost certainly because of better radiotherapeutic techniques (Smith *et al.*, 1961; Bloom *et al.*, 1969; Hope-Stone, 1970). Five-year survival rates as high as 75 % have been quoted (Hope-Stone, 1970) but to the family doctor or neurosurgical unit counselling the newly diagnosed patient, the outlook is confusing as survival is generally quoted after successful completion of treatment. We report the follow-up on 87 of 90 consecutive cases diagnosed in the 10 years 1965–74. Histology in each case was confirmed by Professor T. Crawford at St George's Hospital. Divided into two consecutive 5-year periods there is more than a suggestion that the survival in the 2nd is better.

Cases and methods

Of 90 consecutive cases diagnosed with medulloblastoma in the 10-year period 1965–74, all except 3 cases have complete follow-up. These 3 (described below) are excluded from all the discussion.

Cases lost to follow-up.

Case 1
Girl, complete removal at diagnosis July 1967. Received no radiotherapy or other treatment. No details available since December 1973, when in Malta, alive and well; therefore 6 years after craniotomy, well.

Case 2
Boy, partial surgical removal in November 1969 followed by 5000 rads tumour dose to posterior fossa and 3000 rads to cranium and spinal cord. 14 months after treatment in Qatar in March 1971, said to be blind but otherwise well. No further details.

Case 3
Girl, diagnosed February 1970. Partial removal followed by suboptimal cranial irradiation (3000 rads) and no spinal irradiation. Two months after operation had the insertion of a ventriculo-atrial shunt and was then lost to follow-up in Iran in June 1970.

Cases 2 and 3 have possibly died, but Case 1 is a 'long-term' survivor.

Cases with complete data.

Sex
52 boys and 35 girls.

Age
Three months to 11 years, median 4 years.

Length of symptoms before diagnosis
One week to greater than one year, median < 3 months.

St George's Hospital, London
N. McINTOSH, consultant paediatrician

Symptoms

These were well described recently by Gjerris (1976). Symptoms of many of the cases in this series were discussed previously by Till (1975).

Surgery

Definitive surgery was carried out in 94% of cases at The Hospital for Sick Children in London. As a routine this consisted of posterior fossa decompression with removal of as much tumour as the surgeon considered possible at the time of operation. Macroscopic removal was thought complete in 9 (10%) cases and partial in 72 (83%). In all except one, surgery was at the time of initial diagnosis, the exception being a patient referred from Zambia who had received 4 months of chemotherapy (prednisolone, methotrexate, and vincristine) before transfer to England for surgery. Of the 5 cases not receiving definitive surgery, 3 were preoperative deaths and 2 presented with spinal secondaries for which they had laminectomies; one of these 11 months later had a frontal craniotomy for a frontal secondary.

Radiotherapy

11 of 87 patients died before radiotherapy could be initiated, and 2 other patients were not given radiotherapy. Five patients died during radiotherapy. Thus 66 (76%) patients survived the combined treatment of surgery and radiotherapy. Radiotherapy was carried out at 6 different centres—38 cases were treated at UCH, London, receiving treatment with 250 kV equipment until 1967 and subsequently with ^{60}Co equipment. 12 cases were treated at Guildford, before 1968, receiving radiation from 250 kV equipment. 13 cases received treatment at the Royal Marsden Hospital, 3 before 1968 using 250 kV equipment, and 9 after 1968 using 6 MeV equipment. One case was treated at Northampton, one at Nottingham, and one at Derby. Before 1968, radiotherapy was generally with 250 kV equipment and after this date with ^{60}Co or 6 MeV equipment.

Radiation dosage varied, particularly before 1970. The overall outcome of the 87 cases presenting is shown in the Figure.

Table 1 shows how the dosage of radiotherapy has on the whole increased at the various centres in the 2nd 5-year period. Other features of radiotherapy technique have changed. In addition to greater total radiation dosage, better care has evolved by firstly avoiding areas of underdosage of the neuraxis which might allow seeding of tumour cells, and secondly by ensuring no overlap of spinal and cranial fields which might lead to gliosis at the junction of these.

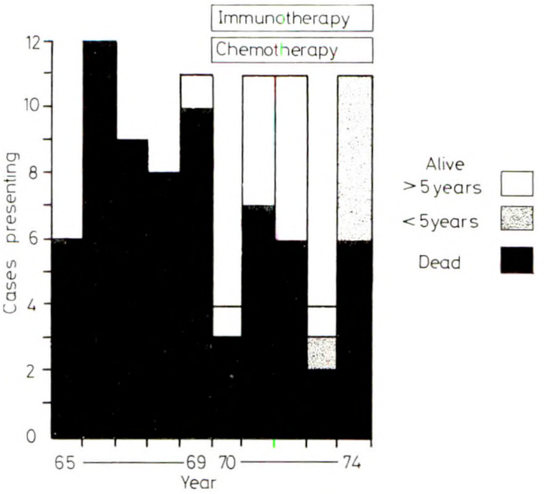

Figure *Outcome on 1 January 1978 for all cases according to year of presentation.*

Table 1 *Dosage of radiotherapy given*

		Adequate treatment	
Period	*Total no.*	*Posterior fossa**	*Spinal cord†*
1965–69	33	10	13
1970–74	33	30	28
		P<0·001	P<0·001

*Adequate treatment posterior fossa = >4000 rads, †spinal cord = >3000 rads.

Immunotherapy (Bloom, 1975)

After 1970 immunotherapy was given to 14 patients as part of a wider trial. Active immunisation was attempted, using autologous medulloblastoma tissue irradiated with 15 000 rads and injected postoperatively subcutaneously. Six injections were normally given during the course of radiotherapy. Seven of these 14 patients are alive, and all are 5-year survivors.

Chemotherapy

12 patients received chemotherapy with their initial treatment and 2 received chemotherapy with recurrence. One case from Zambia had chemotherapy before surgery (see above). The type of chemotherapy varied from one injection of vincristine only to a combination of intrathecal methotrexate, oral CCNU, and IV vincristine in repeated courses. No cases included in the co-operative European trial of adjuvant chemotherapy run by the International Society of Paediatric Oncology (SIOP), which started in January 1975, are included in this series which is complete up to the time of the start of the trial.

Results

The overall outcome of the 87 cases presenting is shown in the Figure. The age range, sex ratio, and length of symptoms before diagnosis are all similar to other extensive series. All except one case diagnosed in the 1st 5-year period died within 4 years, the exception being alive and well 9 years after operation. In the 2nd 5-year period 11 cases are 5-year survivors (39% of those possible), and 6 others are alive and well, although they are not yet 5-year survivors.

All 18 of the current survivors received surgery followed by 5000 rads to the posterior fossa, and 3000–3500 rads to the spinal cord. Seven cases in addition had immunotherapy and 7 chemotherapy. Should complete surgical removal of macroscopic tumour be possible, prognosis is better, 55% are survivors compared with 18% of the partial removal group (χ^2 $P<0{\cdot}01$).

Five survivors are completely well and asymptomatic. Four have features possibly referable to their surgery or radiotherapy, such as visual loss or short stature, and 6 have soft signs such as mild ataxia which could be due to initial tumour damage, surgery, or radiotherapy. Two survivors have severe clinical problems interfering with their everyday life, and both of these have evidence of tumour recurrence.

Two patients presented with secondaries at the time of diagnosis—both are dead. One patient without shunt finally died with extracerebrospinal secondaries in the lung. Secondaries outside the central nervous system are well recorded although rare with this tumour but have never before been recorded within the lung in the absence of a ventriculo-atrial shunt (Makeever and King, 1966).

Table 2 compares the outcome in the two 5-year periods 1965–69, 1970–74. It considers both the total cases presenting and the prognosis in those successfully completing surgery and radiotherapy. The 5-year survival of all cases presenting has improved from 2% in the first period to 39% of those cases in the 2nd period where 5-year follow-up is so far possible. By the χ^2 test these differences are statistically highly significant.

Table 2 *Comparison of survival in the two periods 1965–69 and 1970–74*

Discussion

Cushing, having defined medulloblastoma as an entity, recognised two things about this tumour. Firstly, that there was a high operative mortality and secondly, that without additional radiation, death was invariable within 6 months of diagnosis. The high operative mortality has been confirmed more recently (Smith *et al.*, 1961; McFarland *et al.*, 1969). Elsberg and Gotten (1933) showed that a more conservative approach to surgery consisting of decompression of the posterior fossa with removal of the bulk of tumour tissue and reopening of cerebrospinal fluid paths, gave much better operative figures and did not appear adversely to influence the long-term outcome. This approach, probably associated with advances in anaesthesia and intensive postoperative care, has improved operative and immediate postoperative mortality in this series to 14% (20·5% of the 1st 5-year group and 10·0% of the 2nd group).

The improved survival in the 2nd 5-year period is shown in Table 2. In addition to surgical advances, this improvement could be due to other factors. Firstly, radiation therapy techniques improved in this period with the change from 250 kV to 2–10 MeV or ^{60}Co equipment (Bloom *et al.*, 1969). Secondly, a higher dosage of radiotherapy was applied to both posterior fossa and spinal cord (Table 1) and with awareness was probably applied more effectively. Thirdly, immunotherapy or chemotherapy may have improved the outlook. Because 4 of the survivors had only surgery and radiotherapy, it is likely that improved prognosis is due mainly to improved radiotherapy, not to chemotherapy. This is substantiated by data from the first 100 patients on the SIOP trial of adjuvant chemotherapy in medulloblastoma, where so far there is no difference between patients allocated chemotherapy in addition, compared with the group receiving surgery and radiotherapy alone (Bloom, 1977, personal communication). However, this trial has only been in effect 3 years, so it is too early to draw any conclusions.

The improved techniques of radiotherapy have been described (Smith *et al.*, 1961; Bloom *et al.*, 1969; Hope-Stone, 1970). Hope-Stone in a series of 35 cases, had a 58% 5-year survival but only in a group completing successfully surgery and radiotherapy. The mean age in this series was 9 years which is old compared with other series, and this may favourably have influenced his results.

The reason for the poor survival in the first 5-year period has to be attributed to inadequate radiation, as overall only cases receiving 5000 rads to posterior fossa and 3500 rads to the spinal cord survived. Very few cases in this group received this amount of radiation (Table 1).

For the paediatrician or neurosurgeon counselling parents at the time of diagnosis, it is important to know that the prognosis is improving. At least 39% are now 5-year survivors and overall in this series, no patient has died more than 4 years after diagnosis, although late deaths have occurred in other series (Gjerris, 1976). It may be that 5-year survival will be as high as 46%. By the age + 9 months rule (Collins rule for embryonal tumours) we have overall in the 10-year period 7 (8%) cases cured of their condition (Bloom *et al.*, 1969).

My thanks for encouragement and information from Mr Kenneth Till and Mr Norman Grant, The Hospital for Sick Children, London, Dr Nicholas Godlee and Dr Robert Boyd, University College Hospital, London, Dr H. J. G. Bloom, Royal Marsden Hospital, London, and many other paediatricians.

A controlled trial of cyclophosphamide and azathioprine in Nigerian children with the nephrotic syndrome and poorly selective proteinuria

A. ADENIYI, R. G. HENDRICKSE, AND J. F. SOOTHILL

University College Hospital, Ibadan, Nigeria, and Institute of Child Health, London

SUMMARY In a controlled trial, symptomatic treatment alone, or 12 weeks of cyclophosphamide or azathioprine were compared in Nigerian children with nephrotic syndrome (mainly quartan malarial nephropathy) and poorly selective proteinuria. Full remission in 2 patients in each of the two groups treated with drugs, and diminution of proteinuria in most patients in the cyclophosphamide group showed possible evidence of benefit. Infections during treatment were significantly more common in the drug-treated groups but were controllable. Mortality from renal failure in the 2nd year after treatment was significantly greater in the azathioprine-treated group than in the other two, suggesting that the drug may have exacerbated the nephritis. The 5-year survival rate was similar in the cyclophosphamide and the control group.

Nephrotic syndrome is common in Nigerian children and in most the disease is associated with *Plasmodium malariae* infection (Hendrickse and Gilles, 1963). Renal biopsies show an unusual type of glomerulonephritis (Hendrickse *et al.*, 1972) which is associated with deposition of immunoglobulin, complement, and malarial antigen in the kidney (Houba *et al.*, 1970; Hendrickse *et al.*, 1972). Most such patients do not respond to corticosteroid drugs and may be made worse by them (Hendrickse *et al.*, 1972). A corticosteroid-responsive minority is to be found among cases with less severe renal biopsy abnormality and highly selective proteinuria (Hendrickse *et al.*, 1972; Adeniyi *et al.*, 1976). No effective treatment is yet available for most patients and mortality is high.

Immunosuppressive treatment has been widely used in nephritis but controlled evidence of benefit is available only for corticosteroid-responsive nephrotic syndrome and SLE nephritis. Spontaneous recovery occurs in almost all kinds of nephritis. All the drugs used are toxic and increase susceptibility to infections; this is a serious problem in malnourished communities with poor sanitation.

It has been suggested that susceptibility to nephritis may result from defective antigen elimination because of relative immunodeficiency (Soothill and Steward, 1971). Hence although immunosuppressive treatment may be valuable if it affects the damaging mechanism more than the elimination of antigen, it may make the nephritis worse if the reverse is true. We therefore assessed the effect on Nigerian nephrotic children with poorly selective proteinuria of a standard regimen alone, or with cyclophosphamide or azathioprine (randomly allocated), on proteinuria, survival, and incidence of complications.

Patients and methods

Children with nephrotic syndrome (oedema, heavy proteinuria, and serum albumin <20 g/l) who presented sequentially at this hospital in Ibadan with nephrotic syndrome were divided into one of two groups according to differential protein clearance; those with highly selective proteinuria were included in a study of corticosteroid response (Adeniyi *et al.*, 1976).

The present study was on 36 children (23 boys and 13 girls) aged between 2 and 12 years who had poorly selective proteinuria, clearance of IgG over clearance of albumin (CG/CA) >15%.

The patients were randomly allocated. Each drew a sealed card from a box, giving the name of one of

the three groups—azathioprine, cyclophosphamide, or control. Cyclophosphamide was given orally as a single daily dose of 3 mg/kg per day for 12 weeks and azathioprine 2·5–3 mg/kg per day similarly for 12 weeks. Haemoglobin, packed cell volume (PCV), white blood count (WBC), platelet counts, and differential protein clearance were done on all patients before starting treatment; a renal biopsy was done before treatment started in most of them.

Proteinuria was detected in urine by Albustix, and was graded O, ±, + to 4 + according to the manufacturer's scale. Differential protein clearance studies were performed on random samples of plasma and urine obtained at the first visit to hospital by the single radial gel diffusion technique (Adeniyi *et al.*, 1976). Plasma albumin was standardised using a previously calibrated serum standard. PCV, WBC, and platelet counts were done 6 times in the first two weeks of treatment, and then at each visit. Renal biopsies were classified as previously described (Hendrickse *et al.*, 1972).

Management. All patients entering the trial were in hospital for at least 2 weeks for diagnosis and starting treatment. They were then followed up at the outpatients department where they were seen every 2 weeks for 12 weeks, when cytotoxic treatment was stopped in most, after which they were seen less often for up to 5 years.

All patients were initially treated for malaria with a combination of chloroquine and primaquine, and received a high protein, low sodium diet, and the diuretic hydroflumethiazide. At each outpatient attendance drugs to last until the next visit were dispensed and any unused tablets were brought back to check on correct drug dosage at home. Patients were instructed to return immediately in the event of any untoward reactions or intercurrent illness. Full clinical examination, including blood pressure, was done at each visit and any illness was promptly treated, with hospital admission if necessary.

Results

There was no significant difference in ages, plasma albumin levels, CG/CA, or renal biopsies in the three groups. *P. malariae* were seen in blood films from 27 of the 36 patients. Blood urea and serum electrolytes were within normal ranges and only one patient had a blood pressure > 120/80mmHg at the first visit. 31 patients had renal biopsies; in all the lesions were characteristic of quartan malaria nephropathy. Immunofluorescence examination was positive for IgG in all 27 studied, and in all but one for C3.

Two patients treated with cyclophosphamide and 2 treated with azathioprine had complete clinical remissions with loss of proteinuria (trace or 0) by the 8th week of treatment, but none in the control group. Of these the 3 in whom biopsy was done showed mild QMN lesions, positive for IgG and C3. All patients showed a rise in serum albumin which was probably due to better feeding. Six other patients treated with cyclophosphamide improved considerably, as shown by loss of oedema, rise in serum albumin to normal levels, and reduction in proteinuria (Albustix + on 3 consecutive urine testings), which reflects a substantial reduction of albumin clearance (Table 1). The other children had no reduction of proteinuria detectable by these tests (Albustix 3+ 4+) and serum albumin remained well below 20 g/l. More patients in the cyclophosphamide-treated group improved than did those in either the control or the azathioprine group.

The cytotoxic drugs had a number of adverse effects. Some patients complained of anorexia, nausea, and vomiting when either drug was given in the morning, but this was overcome by giving it at night. It was necessary to withdraw cyclophosphamide in 2 patients, in one because of severe haemorrhagic cystitis and in the other (subsequently shown to have severe renal amyloidosis) because of rapid deterioration, severe skin infection, bronchopneumonia, and septicaemia. Both drug-treated groups had significantly more infections than the control group. The main infections were of the skin and bronchopneumonia (Table 2). The organisms most often isolated from skin lesions were *Staphylococcus aureus*. The patients responded to treatment with antibiotics to which organisms were sensitive.

No patient died during the drug treatment period and in none did PCV, WBC, or platelet counts fall below normal limits.

Regular outpatient follow-up was planned for 5 years after the treatment. Some patients did not attend, and attempts were made to get into contact with them at home. The 5 patients who did not attend and were not traced, and who had had hypertension and raised levels of blood urea on the last visit, have been classified as presumed dead; one with normal blood pressure and blood urea after full remission at 4 years was presumed alive at 5 years. The 4 patients who had complete remissions remained well throughout follow-up. The mortality in the 5 years of follow-up is shown in the Figure. Only one child died in the first year (of renal failure due to renal amyloidosis). There were significantly more deaths in the azathioprine-treated group than in the other two, in the 2nd year of the follow-up (Table 1). There was no obvious relationship between time of death and the initial renal biopsy histology or differential protein clearance. In most children who died, death was preceded by hypertension and raised levels of blood urea and the deaths were regarded as being due to renal failure. At necropsy contracted kidneys were found in all.

The 4 patients who showed rapid disappearance of proteinuria remained well and free of proteinuria throughout the period of follow-up. The diminished proteinuria initially observed in the cyclophosphamide-treated group appears to have had no influence on prognosis as, after 2 years, mortality rose and was similar to that in the control group but was still lower than in the azathioprine-treated group.

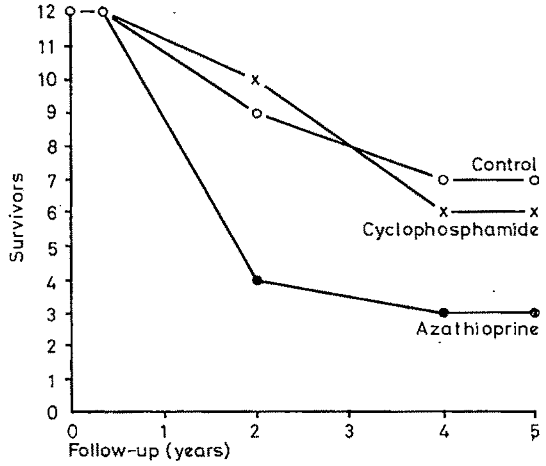

Figure *Number of nephrotic children in each group surviving at each follow-up period. The allocation of nonattenders is explained in the text.*

Since completing the trial cyclophosphamide has been used in 13 more such patients, and the same procedure was used. Three lost their proteinuria and 4 showed considerable reduction. Three other patients with nephrotic syndrome were given cyclophosphamide in gradually increasing doses until neutropenia (WBC $<3000/\text{mm}^3$; $<3\cdot0\times10^9$/l) resulted when the drug was discontinued. No therapeutic benefit was noted. In 9 other patients treated with azathioprine no benefit of treatment was noted.

Discussion

The findings in this study confirm previous reports of the gravity of the prognosis in nephrotic syndrome in Nigerian children and the generally poor response to immunosuppressive treatment. Kibukamusoke (1968) reported an impression of benefit from treatment with azathioprine, not found in this or in previous studies undertaken in Ibadan (Adeniyi *et al.*, 1970). Our findings show that azathioprine does not generally control proteinuria, and that its use is associated with a much higher risk of infection and a significant reduction in the 2-year survival rate. On the available evidence, azathioprine must be regarded as contraindicated in the treatment of nephrotic syndrome in West African children.

The increased mortality due to renal failure observed in patients treated with azathioprine is interesting and could be an example of the postulated system in which a drug may accelerate renal disease by causing more damage to mechanisms concerned with antigen clearance than to the mechanism causing the renal damage (Soothill and Steward, 1971; Steward *et al.*, 1973). Some of the changes observed in immunofluorescence findings on renal biopsies in some azathioprine-treated cases of nephrotic syndrome (Houba *et al.*, 1970) could be interpreted as having arisen from such an effect.

Cyclophosphamide treatment was associated with remission in 2 patients and a significant reduction of proteinuria in the group as a whole, but this was not associated with improved survival; there were serious side effects during treatment, especially infections. The absence of full remission in the control group and our previous experience, suggest that the occasional complete remission may be an effect of cyclophosphamide, and that response is more likely in those with a relatively short history (< 3 months), and relatively mild histological lesions (QMN grade I, Hendrickse *et al.*, 1972). It seems sensible, therefore, to limit the use of this drug to patients who satisfy these criteria, and who can be closely supervised during treatment. Selectivity of proteinuria, useful for predicting corticosteroid response in

Nigerian nephrotic children (Adeniyi *et al.*, 1976) does not predict recovery after cyclophosphamide in those with relatively poorly selective proteinuria.

Serum gastrin levels in hypertrophic pyloric stenosis of infancy

Response to a gastrin secretion test

MICHEL A. HAMBOURG, M. MIGNON, C. RICOUR, J. ACCARY, AND D. PELLERIN

Department of Paediatric Surgery, Hôpital des Enfants Malades, and Gastroenterology Research Unit, Hôpital Bichat, Paris

SUMMARY The aim of this study was to look for a difference in fasting serum gastrin levels or in serum gastrin response to oral feeding between infants with hypertrophic pyloric stenosis and normal controls. Fasting serum gastrin levels were measured by radioimmunoassay in 10 patients with pyloric stenosis, before pyloromyotomy and 7 and 15 days after it, and in 11 controls. In addition, the serum gastrin responses to a casein hydrolysate meal were studied in both groups (in the patients, 7 days after operation). The fasting serum gastrin levels in the patients did not differ from those in the controls before operation, but they did so after it. The serum gastrin response to feeding in patients after pyloromyotomy was no greater than in controls.

Since the introduction of sensitive methods for measuring gastrin (McGuigan, 1968; Yalow and Berson, 1970), this hormone has been studied in normal children (Sann *et al.*, 1975; Niessen *et al.*, 1976) and it is suggested that serum levels vary with age. The mechanisms responsible for the secretion of gastrin are present at birth. Serum gastrin level is higher in the blood of neonates than in peripheral maternal blood (von Berger *et al.*, 1976; Euler *et al.*, 1977), and rises after the first feed, continuing to rise steeply for a few days after birth (Rogers *et al.*, 1974). The hypothesis that increased gastrin secretion may induce hypertrophic pyloric stenosis in infancy receives support from experimental studies. Pyloric stenosis has been observed in newborn pups after repeated injections of pentagastrin to pregnant bitches during the final stages of gestation, and the most pronounced changes were seen in 30-day-old pups that continued to receive pentagastrin after birth (Dodge, 1970; Karim *et al.*, 1974; Dodge and Karim, 1976). Moreover a direct action of gastrin on the pyloric circular muscle has been demonstrated (Rogers *et al.*, 1976), in addition to an increase of antral mobility induced by the hormone *in vitro* (Bennett, 1965) and *in vivo* (Heinische, 1967; Isenberg and Grossman, 1969). Gastrin released by vagal reflexes may act in newborn babies as a mediator of perinatal environmental stress factors (Dodge, 1975) to produce pyloric contraction or spasm, or both, and pyloric hypertrophy; alternatively the pyloric hold-up could be increased by a self-perpetuating mechanism: antral distension with milk and gastrin release (Dodge, 1972; Rogers *et al.*, 1975).

The presence of hypergastrinaemia in hypertrophic pyloric stenosis has been denied by some investigators (Rogers *et al.*, 1975) and supported by others (Spitz and Zail, 1976). The aim of this study was to determine fasting serum gastrin levels in infants with hypertrophic pyloric stenosis before and after pyloromyotomy. In addition, the serum gastrin response to oral feeding was determined so as to find out whether the response is exaggerated in infants with hypertrophic pyloric stenosis.

A rise in serum gastrin after feeding different milks to normal newborn babies and infants has been shown (Sann *et al.*, 1975; von Berger *et al.*, 1976). It was found that high or pure protein preparations are capable of producing a gastrin release with a

substantial rise in serum gastrin (Konturek *et al.*, 1974). Hydrolysed proteins, and especially free amino-acids, are potent gastrin stimulants (Elwin, 1974; Walsh *et al.*, 1975). There have been no systematic surveys of amino-acids to determine which one releases gastrin. In man, glycine alone has been tested and shown to be a weak stimulant (McGuigan and Trudeau, 1970). The most active releasers of gastrin (serine, valine, and tryptophan) are amino-acids that are rather poor stimulators of acid secretion (Konturek *et al.*, 1977).

Material

After informed parental consent had been obtained the following groups of patients and controls were studied.

Patients. 10 (9 boys and one girl, age range 3 weeks–4 months) infants with hypertrophic pyloric stenosis without radiologically demonstrable gastro-oesophageal reflux.

Controls. 11 (6 boys and 5 girls, age range 3 weeks–4 months) infants with no gastrointestinal or neurological disease.

Development in both groups of babies was normal. All infants were between 3rd and 97th centiles for length as there is evidence relating gastrin levels to body size.

Methods

All blood samples were drawn via an indwelling catheter already in place or by direct venepuncture at the time an indwelling catheter was placed as part of the patient's treatment. 2·5 ml blood was collected in an unheparinised test-tube, with the separated serum stored at −20°C. Serum gastrin was measured by radioimmunoassay (Yalow and Berson, 1970). The specific antisera used were raised by immunisation with repeated injections of synthetic human gastrin 1 (G1 S(1–17)) conjugated to ov-albumin in rabbits. The G1 S1-17 was labelled with iodine-125 (Inserm U 10, Paris) and standard gastrin was obtained from Imperial Chemical Industries Ltd. Separation of bound antibody from free hormone was by dextran-coated charcoal.

Gastrin secretion test. This was performed by administering casein hydrolysate (Amirige, Nutricia, Netherlands) containing 85·5% nitrogenous substances of which 87·5% are polypeptides (di-, tetra-, and hexapeptides) and 12·5% are free amino-acids. The composition per 100 g Amirige was: polypeptides 74·86; free amino-acids 10·84. Essential amino-acids: leucine 1·67; lysine 1·51, methionine 1·33, phenylalanine 1·33, isoleucine 0·15, histidine 0·07, threonine 0·07. Non-essential amino-acids: arginine 1·85, tyrosine 1·71, aspartic acid 0·50, glutamic acid 0·45, serine 0·17.

The compound was prepared in such a way as to contain identical protein concentrations for each infant in the same amounts that he would have received with normal feeding (150 ml of half-cream cows' milk/kg per day containing 132 ml H_2O, 4·20 g protein, and with a caloric value of 103, and given in 6 feeds of 25 ml/kg). The amount of the preparation given at each feed was thus 0·70 g peptides/kg (1 g Amirige = 0·855 g peptides). A 15-min gastric drip feed was used to administer these amounts to each infant after a 6-hour fast. The results in the two groups were recorded and plotted on a curve showing changes in serum gastrin levels at −15, 0, 5, 10, 15, 30, and 60 min from the beginning of the feed. In the patients, gastrin stimulation was carried out on the 7th postoperative day when normal oral nutrition had been resumed. Fasting serum gastrin levels were also determined in these patients before pyloromyotomy and 2 weeks later. The preoperative samples for fasting serum gastrin determination were obtained at least 4 hours after the last feed and the postoperative samples, as in the control group, after a 6-hour fast. Statistical comparison of groups was by Student's *t* test.

Results

Fasting serum gastrin levels. In the control group the mean fasting serum gastrin level (± SEM) was 134·2 ± 18·2 pg/ml. The mean fasting level in the patients before pyloromyotomy did not differ from those in the control group, but these levels did differ ($P<0·025$) after operation. In the patients the mean fasting levels before operation and on the 7th and 15th postoperative days were, respectively, 129·5 ± 23·2, 222·2 ± 39·6, and 197·5 ± 21·7 pg/ml. The differences between the preoperative values and those on the 7th and 15th postoperative days were significant ($P<0·05$ and $P<0·025$ respectively) (Table 1).

Serum gastrin response to feeding. In the control group a substantial rise was noted within the first minutes after the feed with a maximum peak at 10 min, immediately followed by a decline, which was steep to 15 min, becoming more gradual thereafter to 30 min. Basal gastrin levels were regained after 60 min (Fig. 1). The mean basal and peak serum gastrin levels (± SEM) were respectively 134·2 ± 18·2 and 247·5 ± 26·4 pg/ml;

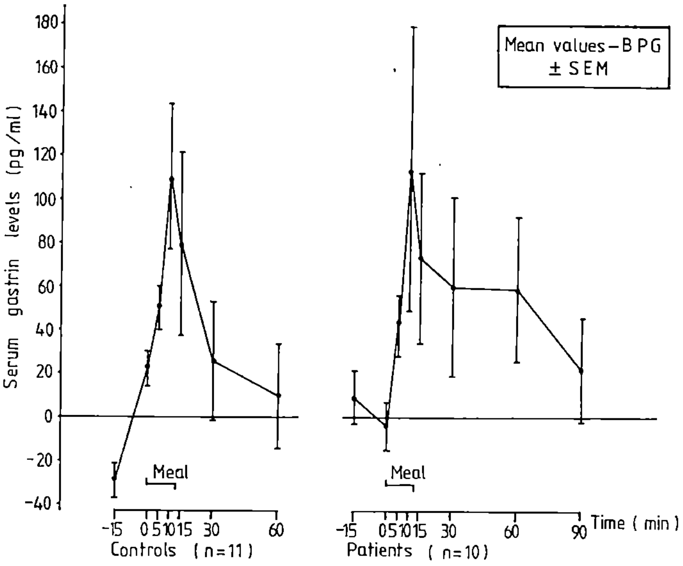

Fig. 1 *Mean serum gastrin levels (pg/ml ± SEM) in 11 control infants and 10 patients with hypertrophic pyloric stenosis after a casein hydrolysate meal. The results are expressed as the mean of all values obtained at each time, less the mean basal serum gastrin levels (BSG) (this explains initial negative values).*

Table 1 *Fasting serum gastrin levels (pg/ml) in 10 patients with hypertrophic pyloric stenosis before and after pyloromyotomy*

Case	*Before operation*	*After operation*

these values differed significantly (P < 0·02) (Fig. 2).

In the patients the serum gastrin response to stimulation was represented by a curve with a levelling-off effect between 30 and 60 min, and a more slowly decreasing slope to baseline value beyond 90 min (Fig. 1). The mean basal and peak serum gastrin levels were 222·2 ± 39·6 and 359·5 ± 56·5 pg/ml, and differed significantly (P<0·02) (Fig. 2).

The peak levels obtained after maximum gastrin stimulation were higher in the patients than in the controls (P < 0·05), but when the increased values were compared as the percentage of basal gastrin levels ((PSG − BSG)/BSG) there was no significant difference (P<0·1) (Table 2). Analysis of the decreasing slope by comparing the mean gastrin

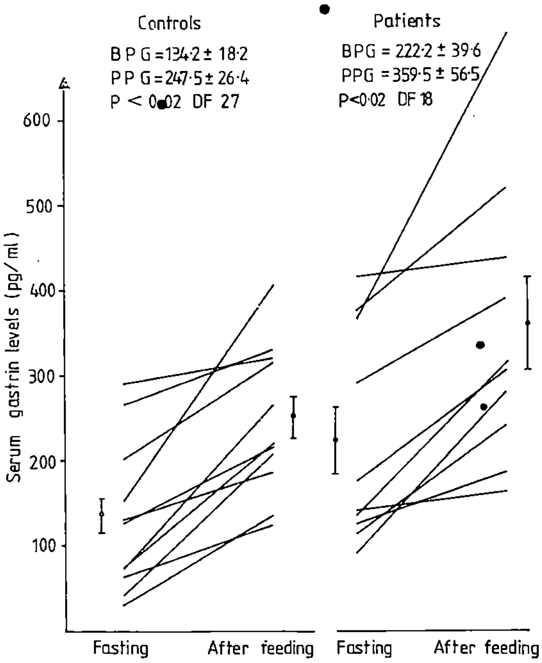

Fig. 2 *Mean basal serum gastrin (BSG) levels and peak serum gastrin (PSG) levels (pg/ml ± SEM) in 11 control infants and 10 patients with hypertrophic pyloric stenosis after a casein hydrolysate meal. The serum gastrin response to the meal is shown by comparing BSG (for each infant, mean value of 2 fasting levels at −15 and 0 minutes) and PSG (for each infant, mean value of the 2 highest levels obtained).*

levels at 30 and 60 min in both groups showed that there was no difference despite the levelling-off effect seen in the patients (at 30 min, $P<0{\cdot}25$; at 60 min, $P<0{\cdot}15$) (Fig. 1).

In patients, increased fasting gastrin levels were present after pyloromyotomy and were still present 2 weeks after the operation. Test meals did not produce an exaggerated gastrin response and the results were of the same order as those obtained by the same trial stimulation in controls.

Discussion

These findings cast doubt on the hypothesis that increased gastrin levels may promote and/or maintain hypertrophic pyloric stenosis of infancy. This doubt is reinforced by the fact that little difference in serum gastrin levels between the healthy and the affected children was found in the preoperative phase.

Nevertheless higher levels were found in the postoperative period. A marked rise in mean fasting levels was also noted 4 and 5 days after operation by Rogers *et al.* (1975) and Spitz and Zail (1976). Such a hypergastrinaemia does not appear to be induced solely by antral distension secondary to pyloric obstruction, as it was still present in our patients 7 to 15 days after pyloromyotomy. This interpretation can be questioned because, although pyloromyotomy relieves clinical obstruction and motility returns within 30 hours (Schärli and Leditschke, 1968), radiological evidence of improvement of the pylorus does not appear until after some weeks or months (Bishop and Hope, 1962). The possibility that distension of the antrum can persist during the postoperative period is therefore not eliminated.

The postoperative hypergastrinaemia could be explained by an inverse relationship between the serum gastrin levels and HCl secretion. Dodge (1976) found that in preoperative children with pyloric stenosis, acid secretion was raised, probably by increased parietal cell mass. This increased acid secretion may decrease basal gastrin secretion by lowering the intraluminal pH. After operation, basal gastric acid secretion falls and it seems that gastrin secretion increases. In our series the fasting gastrin levels showed a significant increase after operation in only 5 out of 10 patients, 3 of whom had the lowest preoperative levels (Cases 5, 6, and 8) (Table 1). Perhaps these low levels indicate that their acid secretion was increased to the point where gastrin release was being inhibited. The reduced gastric acidity found after 7 days would allow these patients to revert to a fasting serum gastrin level more in keeping with their true gastrin secretion level. In any event, these 5 patients responded normally to feeding when tested postoperatively. For obvious reasons the gastrin secretory capacity was not tested in preoperative patients.

Long-term follow-up of patients with pyloric stenosis by Wanscher and Jensen (1971) showed an increased incidence of ulcer symptoms, and many had an increased basal gastric acidity. This might indicate that the hypergastrinaemia persists indefinitely and raises another question, whether hypergastrinaemia is the only long-term result of hypertrophic pyloric stenosis.

Although it was confirmed that gastrin levels after feeding were greater in the patients than in the controls, we would emphasise that the differences are insignificant when they are related to the basal gastrin levels. Thus, our findings do not support the hypothesis that patients with pyloric stenosis may have an exaggerated gastrin response to feeding after pyloromyotomy.

Addendum

Since this paper was written, Janik *et al.* (1977) have confirmed that the wide range of serum gastrin levels in normal infants and children is dependent on age, body surface area, and duration of fast. Rogers *et al.* (1978) failed to demonstrate a significant rise in serum gastrin levels after normal newborn infants ingest protein-containing milk. Werlin *et al.* (1978) measured serum gastrin levels in cord blood of infants in whom pyloric stenosis subsequently developed and in controls, and found little difference.

Transpyloric feeding in the very low birthweight (1500 g and below) infant

One year's experience in an intensive care neonatal unit

IAN BEDDIS AND SHEILA McKENZIE

Hammersmith Hospital, London

SUMMARY The success of transpyloric feeding in a group of babies weighing 1500 g or less was evaluated. This method was successful for most well babies but for many of those who required respiratory assistance (usually by face mask) it was not.

Although babies weighing <1500 g at birth represent only 1% of the total live births in the United Kingdom, they now present the biggest management problem in intensive care baby units. The importance of early feeding and the provision of adequate calories in the first weeks of life has been emphasised (Smallpeice and Davies, 1964; Winick, 1969; Lubchenco *et al.*, 1972). Milk feeding via nasogastric tube is not always satisfactory in the very low birthweight infant, mainly because of the dangers of regurgitation and aspiration. The introduction of jejunal feeding (Rhea and Kilby, 1970; Cheek and Staub, 1973), and the greater use of IV feeding (Shaw, 1973) have, to some extent, made it easier to provide an adequate calorie intake for very small babies. Although there is no controlled evidence, greater experience with total parenteral nutrition may be one of the important factors associated with a higher survival rate of the most immature. Nevertheless milk feeding is likely to have greater application in units with limited laboratory and staff resources as it does not require such frequent monitoring. We report our experience from a neonatal referral unit during a 12-month period when milk feeding was electively practised whenever possible, in the hope that it may help others. This paper presents details of methods of feeding in 69 babies weighing <1500 g at birth who were admitted to the Hammersmith Hospital between 1 January and 31 December 1977.

Patients and methods

During 1977, 95 babies of birthweight 1500 g or less were admitted to the intensive care baby unit. 28 (29%) were born in the hospital, the others were admitted from other units in and near London. The overall survival rate was 53%. In Table 1, the 95 babies are grouped according to birthweights (<1000 g, and 1000–1500 g) and gestational ages (28 weeks or less, 29–30 weeks, 31–32 weeks, and >32 weeks). The number who needed respiratory assistance (RA) (either intermittent positive pressure ventilation (IPPV) or continuous inflating pressure (CIP)) in each subgroup is also shown.

Feeding data on 69 of the 95 babies are presented. The remaining 26 are excluded for the following reasons: 22 died within 4 days of admission (all were ventilated from the time of admission); 3 were admitted when >2 weeks old; one had congenital heart disease and was admitted for a short period only.

The policy in the unit during the period of the study was to feed all babies if possible with milk, expressed breast milk if available otherwise low

solute cows' milk. Apart from 3 babies who were fed entirely intravenously, IV feeding was used only when milk feeds could not be established. Jejunal feeding was attempted in all but the healthiest of babies.

Method of passage of jejunal tubes. The jejunal tubes were made of silicone, weighted with an end-hole stainless steel tip. The outside diameter was 1·7 mm and the inside diameter 0·8 mm. The glabella-to-heel distance was measured and the length marked on the tube with a piece of black cotton. During the first 3 months of the study period, all tubes were passed via the nose. Later an increase in nasal resistance was found in babies with nasal tubes in place (J. Stocks, 1977, unpublished), so the tubes were subsequently passed through the mouth. The tube was passed into the stomach, without an introducer, and the baby was then turned on to his right side; the tube was advanced at intervals varying between 20 min and one hour, depending on how well the baby tolerated the procedure. The position of the tube was checked by introducing 2 ml sterile water down the tube and then aspirating via an orogastric polyvinyl feeding tube. If no water was aspirated the tube was assumed to have passed through the pylorus. (It was not possible to suck back directly via the silastic jejunal tube because suction resulted in the lumen collapsing.) If any doubt remained the position of the tube was checked by *x*-ray.

After feeding had begun the stomach was aspirated every 2–4 hours to ensure that it was free of milk—i.e. the tube had not slipped back.

Attempts were made to pass the tubes as soon as the babies were settled in the unit. IV fluids (5% dextrose in the first 48 hours and dextrose/saline thereafter) complemented the milk intake initially to meet the full daily fluid requirement: 60 ml/kg day 1, 90 ml/kg day 2, 120 ml/kg day 3, 150 ml/kg day 4, increasing to 200 ml/kg at the end of the first week. A supplement of 30 ml/day of water was given to all babies on an open incubator and to those who received phototherapy. No tubes were passed if babies required assisted respiration by face mask, but attempts were made to continue feeding if the tube was known to be in place when the face mask was applied.

Results

Three babies received IV feeding only. The other 66 babies are divided into 3 main groups: group 1, babies fed via gastric tube; group 2, babies fed via nasal jejunal tube; group 3, babies fed via oral jejunal tube. Groups 2 and 3 are subdivided into: (a) those babies requiring no respiratory assistance other than an increase in inspired oxygen; (b) those requiring either IPPV or CIP at some time in the neonatal period.

12 babies were fed via gastric tubes. All but 3 of these were of at least 32 weeks' gestation (mean birthweight 1225 g, mean gestational age 32·4 weeks) and were considered by nursing staff to be well enough to tolerate gastric feeding.

19 babies had jejunal tubes passed via the nose, 35 via the mouth. The mean birthweights of these two groups were 1067 and 1171 g, mean gestational ages 29 and 30 weeks, and the number requiring respiratory assistance was 53 and 57% respectively.

In each case, the time when the feeding tube was first passed, the time taken for it to reach the jejunum, the volumes of milk given, the complications, and the reasons for stopping jejunal feeding were recorded.

Table 2 shows the day on which passage of a feeding tube was first attempted.

The time taken for the jejunal tubes to be satisfactorily positioned is shown in Table 3. Three babies (all <1000 g) in whom jejunal tubes could not be introduced orally because of repeated regurgitation, subsequently had them passed successfully through the nose.

32 babies were fed for at least 3 days and 11 were fed for at least a week. The longest period was 39 days. In 7 babies the jejunal tube was not satisfactorily placed and 6 babies had tubes in place but

were not fed. The reasons for stopping, or not starting jejunal feeds, are shown in Table 4.

In addition to the 5 babies who developed necrotising enterocolitis during jejunal feeding, 3 other babies developed the condition, one while a jejunal tube was being positioned and one after jejunal feeds had been stopped because of apnoea. The time of onset in the third case was not known, the diagnosis being made at necropsy.

Table 4 *Reasons for stopping or not starting jejunal feeds*

	4 passed after RA	Electively stopped Pulled out by baby Out of position after initial satisfactory placement	1 2 1

NEC = necrotising enterocolitis, RA = respiratory assistance (IPPV or CIP).

Intravenous feeding. 22 babies required IV feeding at some time during the neonatal period because of failure to establish milk feeds (6), recurrent apnoea (5), respiratory assistance from birth (6), and necrotising enterocolitis (5). Attempts had already been made in most of these babies to pass jejunal tubes.

In Table 5, a comparison of the mean maximum weight loss, the mean time to regain birthweight, and the mean volume of milk given to the survivors (45 of the 66 babies studied) in the three groups is shown.

Discussion

Until 1975, in this unit, all babies weighing <1500 g at birth, and receiving milk, were fed intragastrically via polyvinyl tubes introduced through the nose. Because of the increasing numbers of small, immature babies, and the impressive success of Rhea and Kilby (1970) with the feeding of babies transpylorically, it was decided to adopt jejunal feeding in preference to IV feeding as we believed that there would be fewer complications.

Because of the association of polyvinyl feeding tubes with perforation (Boros and Reynolds, 1974; Chen and Wong, 1974; Loo *et al.*, 1974), we chose silastic tubing as recommended by Rhea and Kilby (1970). However perforation with a silastic transpyloric tube has recently been described (Pérez-Rodrigues *et al.*, 1978). The silicone paediatric duodenal tubes available on the market are twice the length of our tubes and we felt that this excessive dead space was undesirable, although they are much stiffer and may be easier to pass into the stomach and through the pylorus.

Many babies of birthweights 1500 g or less, will tolerate gastric feeds, and, although this choice of method was purely empirical, the babies fed by gastric tube in this study were healthy, and most were >32 weeks' gestation. We feel it advisable to nurse these babies prone to decrease the risk of aspiration.

Table 5 *Comparison of mean maximum weight loss, mean time to regain birthweight, and the mean volume of milk (ml/kg per day) received on days 1, 2, 3, 4, 7, and 14 between the survivors of groups 1, 2, and 3*

AGA = appropriate for gestational age, SGA = small for gestational age.

The results suggest that we were able to position the jejunal tubes more quickly and satisfactorily when they were passed through the nose, although the figures do not reach statistical significance. Silastic tubes are very compliant and when the oral route was used, the tubes tended to loop out of the mouth and were more liable to be pulled back during suction. Because of the increased nasal resistance (J. Stocks, 1977, unpublished) when tubes are passed through the nose, it was felt that oral tubes were preferable, particularly in the first days of life when very preterm babies are more likely to suffer respiratory disorders. The delay in correct positioning of the tubes by the oral route may explain why babies in group 3 received less milk during the first 14 days than those in group 2.

Overall, 81·5% of jejunal tubes were *in situ* within 72 hours; these figures compare with those of Cheek and Staub (1973) in which 61% of 36 infants were being fed by jejunal tubes within that time, and those of Wells and Zachman (1975) who reported 100% of 18 infants having jejunal tubes in place in less than 48 hours. Rhea *et al.* (1975) found little difficulty in introducing weighted tubes in a large number of infants of varying weights and gestational ages. Rhea and Kilby (1970) found that steel-weighted jejunal tubes were too light to pass through the pylorus and it may be that heavier, gold-weighted tubes would pass more quickly.

32 of 54 babies were fed for at least 3 days and 11 were fed for more than a week, the longest period being 39 days. Difficulties in feeding by jejunal tube were encountered, particularly in the group requiring IPPV or CIP. In most of these, this was administered by the face mask. Nasopharyngeal suction, not only in this group but also in those babies with recurrent apnoea, appeared to play a part in tubes becoming dislodged and this may have accounted for aspiration in 3 babies. Although attention should be paid to the volume of gastric aspirate in all babies, those who require nasopharyngeal suction are particularly at risk of aspirating gastric contents.

During the period of this study 8 babies developed necrotising enterocolitis, 5 while being fed by jejunal tube, one during the time that a jejunal tube was being advanced, one a few days after jejunal feeding had been stopped; in the last case, the diagnosis was made at necropsy. The part played by jejunal feeding in a condition of probable multiple aetiology is difficult to assess although alteration of bacterial flora in the jejunum with jejunal tubes (Challacombe, 1974) or local irritation may predispose to the condition.

We suggest that jejunal feeding is best used for as short a period as possible because not only is this method of feeding unphysiological but it also has recognised complications. In addition, continuous infusion of milk directly into the jejunum may alter the intestinal bacterial flora. Oral feeding with umbilical arterial catheters in place may also predispose to necrotising enterocolitis (Lehmiller and Kanto, 1978).

Babies with birthweights of 1500 g and less admitted to this unit between 1965–70 were fed by gastric tubes only (Davies and Davis, 1970; Davies and Tizard, 1975) and it is interesting to note that although those babies received a greater volume of milk/kg per day in the first 14 days of life compared with ours, the percentage weight loss and time to regain birthweight were similar. However, the much better survival rate in 1977, in addition to the use of IV feeding, and a number of other factors, all make direct comparison difficult.

This study shows that naso- or orojejunal feeding can be successfully carried out in well babies of birthweights <1500 g. However, this method of feeding for babies requiring respiratory assistance almost entirely by face mask was not successful, and such babies may benefit from a period of IV feeding until respiratory assistance is no longer required. Only 2 out of 24 babies were successfully fed while receiving respiratory assistance. Our principal complication was aspiration (3/54) but it is impossible to know if this would have been more or less with gastric feeds. It should be emphasised that intravenously feeding very low birthweight babies is not without difficulties and is best carried out in the specialised units experienced in the procedure.

We should like to thank Dr Pamela Davies for her advice in the preparation of this paper and the nursing staff of the premature baby unit for their co-operation during the study.

Lysozyme in the tears of newborn babies

P. C. ETCHES, F. LEAHY, D. HARRIS, AND J. D. BAUM

John Radcliffe Hospital, Oxford

SUMMARY Tear lysozyme concentration was measured in term, preterm, and small-for-dates infants using a modification of the lysoplate technique. The lysozyme concentration was greater in the term infant than in preterm and small-for-dates infants. The values were found to increase with birthweight and gestation to a term value which is similar to that described in adults. There was no relationship between the lysozyme concentration and the rate of tear production.

In 1922 Fleming discovered 'a remarkable bacteriolytic element' in nasal mucus which was capable of lysing certain bacteria, particularly *Micrococcus lysodeikticus*, which he called lysozyme. The lysozyme is identical in all human secretions and tissues but lysozyme in hen egg white is different (Jollés and Jollés, 1967). Lysozyme acts by breaking down cell wall mucopolysaccharides; this action has been precisely defined and this group of enzymes can be classified as muramidases or N-acetylmuramide glycanohydrolases (Chipman and Sharon, 1969). One source of human lysozyme is in the urine of patients with monocytic and myeloid leukaemia (Osserman and Lawlor, 1966). However, lysozyme is an enzyme that is found in many secretions, including human milk and human tears (Jollés and Jollés, 1967).

Sticky eyes are common in newborn infants. As a possible predisposing factor to eye infections, we wondered whether there was any deficiency in the lysozyme activity in neonatal tears. The concentration of lysozyme in adult human tears has been measured (Friedland, *et al.*, 1972; Pietsch and Pearlman, 1973; Mackie and Seal, 1976), but there has been no systematic study of the amount present in the tears of newborn babies.

Patients

Three groups of infants were studied: 20 term infants of appropriate weight for gestation, 17 preterm infants appropriate in weight for gestation, and 10 term infants who were small-for-dates (Table). Gestational age was based on the date of the mother's last menstrual period or, if this was not known, on the baby's physical and neurological characteristics (Dubowitz *et al.*, 1970). We took samples from normal uninfected eyes within the first 24 hours after birth. In most cases the baby lay quietly sleeping while samples were collected. Permission for the study was granted by the Oxford Area Health Authority (Teaching) Ethics Committee, and in each case parental permission for collecting the samples was obtained.

Table *Characteristics of the three groups of babies*

	Term (*n* = *20*)	*Preterm* (*n* = *17*)	*Term* (*small-for-dates*) (*n* = *10*)

Range	2·72–4·04	1·05–3·12	2·02–2·81
Gestation (weeks)			
Mean	39·8	33·7	38·9
Range	37–41	28–36·5	37–41

Method of measuring tear lysozyme concentration

The tears were collected by the method described by Schirmer (1903). A commercially available standardised sterile strip of filter paper (Schirmer tear test: SMP International Inc.) was bent at a right-angle at the notch, 5 mm from one end. This was gently hooked over the lower lid so that the short rounded 5 mm portion was resting in the lower conjunctival sac at the medial side of the eye. After exactly 5 minutes the strip was removed and the length beyond the notch which had been wetted by tears was measured. Occasionally, if the rate of tear production was high, the strip was removed when the whole of its length (30 mm from the notch)

became wet, and the time noted. In this way we obtained a crude index of the rate of tear production, as well as obtaining a sample of tears.

'Lysoplates' were prepared according to a modification of the method of Bonavida and Sapse (1968). 1% mass/vol. agarose was dissolved in 0·066 mol/l sodium phosphate buffer, pH 6·24, containing 1% sodium chloride, by heating in a boiling water bath until the agarose dissolved. This solution was cooled to 65°C and a thick suspension of *M. lysodeikticus* added to make the concentration of cells 0·05%. 10 ml of this mixture was placed in each plate, solidified at room temperature, and stored at 4°C.

The lysoplate technique depends on the measurement of the diameter of the zone of lysis in the *M. lysodeikticus* suspension produced by the lysozyme which is placed on the surface of the agarose and incubated at 37°C. Others have taken a 5 mm length of the Schirmer strip, but we found by weighing that this produced a piece of paper which varied greatly in size and therefore would carry a variable quantity of the solution. We therefore constructed a circular punch to produce discs of filter paper 4 mm in diameter so as to standardise the loading volume. To establish that this did, in fact, standardise the loading volume, a 4 mm disc was punched 5–10 mm from the notched end of a strip which had been wetted by dipping the notched end in water. The water-loaded disc was weighed on a balance accurate to one microgram. The disc was reweighed after it had dried and hence the amount of water taken up was obtained. In a series of 25 pilot experiments the mean weight of the disc was 0·975 mg (SD ± 0·086). These discs took up water with a mean weight of 1·298 mg (SD ± 0·233). We then found that a standard solution dried in air at room temperature resulted in no loss of lysozyme activity.

Other workers (Bonavida and Sapse, 1968; Peeters and Vantrappen, 1977) have drawn attention to the problems of the lysoplate method. The time of incubation (24 hours) and the temperature (37°C) are important as are the pH and ionic strength. It is important to use agarose and not agar because lysozyme binds to the latter but not to the former (Bonavida *et al.*, 1967). The thickness of the agarose in the plate is important as is the micrococcus concentration: it is preferable to use the same 'batch' of plates throughout. We showed that there was no variation in the zone of lysis produced by a lysozyme standard disc when plates were stored for a period of 4 weeks at 4°C.

A calibration curve was constructed from known standards of human lysozyme. All samples were measured using a single 'batch' of plates and an internal standard was included in each case.

Results

The rate of wetting of the strip in mm/min was used as an index of the rate of tear production and plotted against the zone of lysis; there was no correlation demonstrable. This indicates that an alteration in the rate of tear production does not affect lysozyme concentration.

Fig. 1 shows the distribution of the zones of lysis (corresponding to the lysozyme concentration) produced from each eye from each patient in the three groups (one sample was lost from one preterm infant). The zone of lysis is significantly greater in the term babies compared both with the preterm babies and the small-for-dates babies.

The zone of lysis against gestation is shown for appropriate weight for gestation babies in Fig. 2. The lysozyme concentration increased with increasing gestational age. The mean zone of lysis for term babies, 27·3 mm, corresponds to a lysozyme concentration of 1118 µg/ml. Fig. 3 shows the zones of

lysis plotted against birthweight for all babies, including the infants born at term small-for-dates. The lysozyme concentration increases with increasing birthweight.

Discussion

There are at least 7 tear proteins (Josephson and Weiner, 1968; Sapse *et al.*, 1969) of which the main components are pre-albumin, lysozyme, lactoferrin, and immunoglobulin A (Broekhuyse, 1974). Ridley (1928) described the bactericidal action of tear 'lysozyme' on a wide variety of micro-organisms and it later became clear that although lysozyme may be effective and protective against some pathogenic bacteria, the concentration has only to be decreased slightly for it to become ineffective (Ridley, cited by Regan, 1950). Thompson and Gallardo (1941) found that the antistaphylococcal action of tears was destroyed by acidification and heating, although the lysozyme content remained unaltered. Subsequently Friedland *et al.* (1972) demonstrated a potent 'non-lysozyme antibacterial factor' in tears.

The normal values for human tear lysozyme in adults was found by Bonavida and Sapse (1968) to be about 1700 μg/ml, although the values in their 4 infants were less (700–800 μg/ml). The mean result for our term infants was 1118 μg/ml which lies between these two values. However, the concentration of tear lysozyme varies with both gestation and birthweight.

In 1928 Ridley found a decreased lysozyme activity in certain eye diseases, including epiphora, and other workers have subsequently confirmed this (Sapse *et al.*, 1968; El-Gammal and Mostafa, 1971). One suggestion has been that an increased flow of tears produces a dilution effect. In normal eyes, however, Mackie and Seal (1976) showed very little difference in lysozyme concentration between slow and fast tear producers, and our results with neonates are similar.

It seems that newborn infants without eye infections have no marked deficiency of tear lysozyme. Preterm infants are not generally thought to be especially prone to eye infections, yet the lysozyme concentration in tears is lower with shorter gestation.

However it is likely that tear lysozyme represents only one of a wide range of synergistic antimicrobial factors. We have no additional information on these other factors in the newborn eye, nor on how the levels of lysozyme and nonlysozymal factors behave in infants with conjunctivitis.

We thank Dr Colin Black of the Department of Zoology, Oxford, for advice and supplying the human lysozyme; Mr Anthony Bron, reader in ophthalmology, Oxford, for his advice; Mrs Alison Smith for statistical help; and Mr P. Goddard for making the circular punch for producing discs from the Schirmer strips.

Lomotil poisoning in children

J. A. CURTIS AND K. M. GOEL

Royal Hospital for Sick Children, Glasgow

SUMMARY 45 children were admitted to hospital after ingesting varying quantities of diphenoxylate (Lomotil). One died and 44 recovered without any sequelae. Four patients were comatose, 32 were drowsy, and 9 suffered respiratory depression. No correlation was found between ingested dose and the severity of symptoms. Because of its action in rendering the gut atonic, removal of diphenoxylate by gastric lavage is mandatory, even in patients admitted at least 24 hours after drug ingestion. Naloxone is the narcotic antagonist of choice, and should be used in all cases where suspected diphenoxylate poisoning leads to respiratory depression or coma. The use of Lomotil as an antidiarrhoeal agent in children is difficult to justify.

Diphenoxylate (Lomotil), widely used for the symptomatic relief of diarrhoea, was first marketed in America in 1961, each tablet or 5 ml of syrup containing diphenoxylate hydrochloride 2·5 mg and atropine sulphate 0·025 mg (Ginsburg, 1973). The atropine was added to discourage narcotic abuse by causing unpleasant effect in excessive dose. It was first marketed in the United Kingdom in 1963. Although there are few adverse reactions in adults, Lomotil may result in serious toxicity in children. Effects from the atropine are often present for about 3 hours until the narcotic-like actions of diphenoxylate hydrochloride begin to predominate. Respiratory depression is the most dangerous development and should be treated with narcotic antagonists and other supportive measures. The purpose of this paper is to present 45 cases of Lomotil poisoning in children and to describe its management.

Patients and methods

Between September 1966 and March 1978, 45 children (28 boys and 17 girls) were admitted to hospitals in Glasgow with Lomotil poisoning (Figure). Ages ranged between 10 months and 6¾ years, with a mean of 2½ years. The number of children from social classes I to V were 4, 14, 11, 8, and 8 respectively. In only 6 cases was the Lomotil prescribed for a diarrhoeal illness in the child and in 4 of these the child took an accidental overdose. In 30 (67%) cases the Lomotil had been prescribed for an adult relative, but in the other 9 children it was not known for whom the Lomotil was prescribed.

The clinical features of Lomotil poisoning in our patients are given in Table 1. These, on clinical grounds, were divided into three groups, according to whether the symptoms were mild, moderate, or severe. Those mildly affected had features of atropinism only—namely tachycardia, flushing, pyrexia, mydriasis, urinary retention, restlessness, and excitement. Those with moderate symptoms were drowsy and may also have had respiratory depression, while those classified as severely affected were unconscious. Using these criteria, 2 patients were unaffected, 7 were mildly, 32 moderately, and 4 were severely poisoned (Table 2). An average of 3 hours elapsed between ingestion of the drug and onset of symptoms. No correlation was found between the dose ingested and severity of symptoms. In fact, the mean dose of diphenoxylate and atropine was greater in the group with mild symptoms (2·9 and 0·029 mg/kg) than in those moderately affected (2·3 and 0·023 mg/kg), while in the severely poisoned group the dose of diphenoxylate and atropine ranged from 0·77 to 10 mg/kg and 0·007 to 0·10 mg/kg respectively. One patient in the last group, a 2-year-old

boy, ingested possibly 27 Lomotil tablets (5·6 mg/kg diphenoxylate and 0·05 mg/kg atropine) at 7 p.m. He apparently showed no ill effects 3 hours later and so his parents put him to bed. He could not be roused the next morning at 10 a.m. and was found to be deeply comatose with laboured breathing on admission. His level of consciousness and respirations improved after 5 mg nalorphine IV but, 3 hours later without having regained consciousness, he had a respiratory arrest and was ventilated. Despite hourly injections of 0·08 mg naloxone IV he showed no subsequent response, his condition being marked by deepening coma and papilloedema. He died 48 hours after admission. Necropsy examination showed atropine in the liver 4 days after drug ingestion. Of the 9 children with respiratory depression, 2 required continuous ventilatory support. 40 patients had gastric lavage performed but, in the fatal case, this was not carried out until 26 hours after the drug was ingested. Five patients were given nalorphine (2–35 mg) and 3 naloxone (0·08 mg) as a narcotic antidote, with beneficial effects on respiratory state or level of consciousness in each case. Of those poisoned, 37 made a full recovery within 24 hours while the remaining 6 were drowsy for a longer period.

Discussion

Of the 45 patients admitted between 1966 and 1978, 29 (64%) were admitted during the last 5 years. This trend occurred despite attention being drawn to the dangers of Lomotil intoxication (*British Medical Journal*, 1973). Lomotil is an effective and safe drug for the treatment of diarrhoea in adults

Table 2 *Severity of symptoms of Lomotil toxicity*

Symptoms	*Patients (n=45)*	*Age range (years) (mean)*	*Dose ingested (mg/kg)*			*Outcome (recovered n=44)*
				Range	*Mean*

			Atropine sulphate	0·007–0·10	0·047	

*Age and amount ingested not known in one patient.

(Wasserman, 1974). Its safety for young children, however, is open to question. While the amount of atropine sulphate is very small for the adult patient, children can develop atropinism even with normal dosage (Wasserman *et al.*, 1975). Furthermore, in children there is a very narrow range between therapeutic and toxic dosage and they may exhibit an intolerance to the drug (Bovier-Lapierre *et al.*, 1973; Scorza *et al.*, 1974). We were unable to find a correlation between the severity of symptoms and the dose ingested. Because of this it is not possible to predict what dose will be toxic in children, and while some may have only the mildest symptoms with relatively large doses, others develop severe toxicity on ingesting an amount near the normal dose. In our series in each group of poisoned patients there were children who had ingested small and some who had taken relatively large amounts of the drug (Table 2). Furthermore, analysis of reported cases of Lomotil intoxication confirms the absence of any relationship between the ingested dose and the intensity of subsequent symptoms (Table 3). This is also evident in considering the fatal cases where one patient succumbed to a dose of 5·6 mg/kg diphenoxylate, while the patient cited by Ginsburg and Angle (1969) ingested only 1·3 mg during a 24-hour period. Because of its action in rendering the gut atonic, Lomotil is slowly absorbed once peak plasma levels are reached (at 2 hours) and its excretion is prolonged by an enterohepatic circulation (Karim *et al.*, 1972). Therefore delay in onset and recurrence of symptoms are both features of overdosage (Henderson and Psaila, 1969; Riley, 1969; Wheeldon and Heggarty, 1971). Because of the difficulty in predicting the clinical outcome, all children who have ingested Lomotil in excess, or who show features of toxicity from therapeutic amounts of the drug, must be admitted for observation for a period of at least 24 hours.

The diagnosis of Lomotil poisoning is not aided by the laboratory as the rapid conversion of diphenoxylate to diphenoxylic acid renders it undetectable in blood or urine although atropine may be detectable in biological fluids. Our patient who died had traces of atropine in the liver 4 days later, but diphenoxylate was not detectable in any of the biological fluids. Therefore lack of laboratory detection has some major implications for treatment of suspected Lomotil poisoning. However all patients suspected of Lomotil poisoning must have gastric lavage performed, irrespective of the length of time after ingestion and of whether or not emesis has occurred, to ensure maximum gastric emptying (Rumack and Temple, 1974). Activated charcoal may adsorb diphenoxylate and can be left in the stomach in a dose of 2 g/kg (Corby *et al.*, 1970). The administration of an emetic is probably undesirable because of the rapidity with which the patient may become apnoeic and drowsy, thus increasing the possibility of aspiration. Although atropine is removed from the body more rapidly by forced diuresis, this is an ineffective way of increasing diphenoxylate excretion (Way, 1968). Similarly there is no evidence that haemodialysis, peritoneal dialysis, or exchange transfusion will adequately remove significant quantities of diphenoxylate or its metabolites. The appearance of either respiratory depression or drowsiness is the signal for the use of a narcotic antagonist. Naloxone is the drug of choice as it does not cause respiratory depression (Evans *et al.*, 1973). The recommended dose of naloxone is 0·005 to 0·1 mg/kg given intravenously, intramuscularly, or subcutaneously and this dose may be repeated at intervals of 2–3 min according to clinical response. Since its duration of action is much exceeded by that of diphenoxylate it may need to be given frequently as its effect tends to diminish after about 2–3 hours. Therefore overdoses should be treated promptly with gastric lavage, and intensive monitoring of the patient's respiratory and conscious state during the first 24 hours is mandatory.

As in 67% of our cases Lomotil had been prescribed for an adult relative, parents should be instructed to keep the drug out of the reach of

children and any remaining tablets should be returned to the chemist as soon as the illness is over. Some of our patients took tablets which had been prescribed some time before by the general practitioner. Needless to say, the doctor should prescribe these tablets in limited quantities.

Although the manufacturers indicate that Lomotil is contraindicated in children under age one year, we doubt if it has any place in the treatment of diarrhoea in children.

We are grateful to our colleagues for allowing us to study patients under their care.

Paper given at the Summer Meeting of the Scottish Paediatric Society held at Ninewells Hospital, Dundee, 2 June 1978.

Foot length—a new and potentially useful measurement in the neonate

DAVID K. JAMES, ELIZABETH H. DRYBURGH, AND MALCOLM L. CHISWICK

St Mary's Hospital, Manchester

SUMMARY The foot length, occipito-frontal head circumference (OFC), crown-rump, and crown-heel length (CHL) of 123 neonates of gestational ages 26–42 weeks, were measured between 12 hours and 5 days. A gauge, designed and constructed at St Mary's Hospital, Manchester, was used to measure foot length. In term babies (37–42 weeks) who were of weights appropriate for gestational age (AGA) the scatter about the mean of foot length measurements was small (coefficient of variation = 4·5%) compared with birthweight (coefficient of variation = 12·0%). The wide range of foot length measurements in babies of different gestational ages prevented maturity being accurately estimated. The mean birthweight of term light-for-dates (LFD) babies was 30·9% lower than term AGA babies, whereas the mean foot length, OFC, and body length of LFD babies was reduced by only 4·2–8·8%. There was a positive linear correlation between foot length and other indices of body size in LFD and AGA babies of all gestational ages. However, in premature babies (<37 weeks) the correlation between foot length and birthweight (r = 0·95) and foot length and CHL (r = 0·96) was pronounced. The 95% confidence limits of the regression lines were ± 327 g and ± 2·3 cm respectively. Birthweight and CHL of premature babies can therefore be estimated from a measurement of foot length that is performed simply and rapidly. Measurements of foot length are valuable in premature babies who are too ill at birth for conventional anthropometric measurements to be made, and in whom such measurements cannot be carried out subsequently because of the encumbrance of the incubator and intensive care apparatus. Drug dosages and intravenous fluid requirements based on body weight or surface area can be indirectly calculated from a measurement of foot length.

Certain ill newborn babies, particularly those that are premature, require intensive care from the moment of birth. It is rare for measurements such as birthweight, body length, and occipito-frontal head circumference (OFC) to be made because priority is given to life support. It is virtually impossible to gain access to these babies for anthropometric measurements because they are nursed in incubators and attached to monitoring devices, intravenous infusion lines, and often to mechanical ventilators. Yet the dosages of various drugs and intravenous fluid requirements are based on body weight or surface area.

The foot is usually readily accessible for measurement of its length, even in premature babies, nursed in incubators, and receiving intensive care. There is a positive correlation between foot length and height in adults (Dahlberg and Lander, 1948; Helmuth, 1974). Foot length in the fetus is closely correlated with body length (Pospisilova-Zuzakora, 1962) and gestational age (Markowski and Lawler, 1977). We studied foot length measurements in the newborn as a method of estimating other anthropometric indices.

Patients and methods

A neonatal foot length gauge (Fig. 1) was designed by one of us (D.K.J.) and constructed in the hospital workshop (Department of Medical Physics). It is made from Perspex and consists of a platform against which the baby's heel is placed, and a sliding bar which makes contact with the tip of the big toe. The scale beneath the sliding bar has a range from 2 to

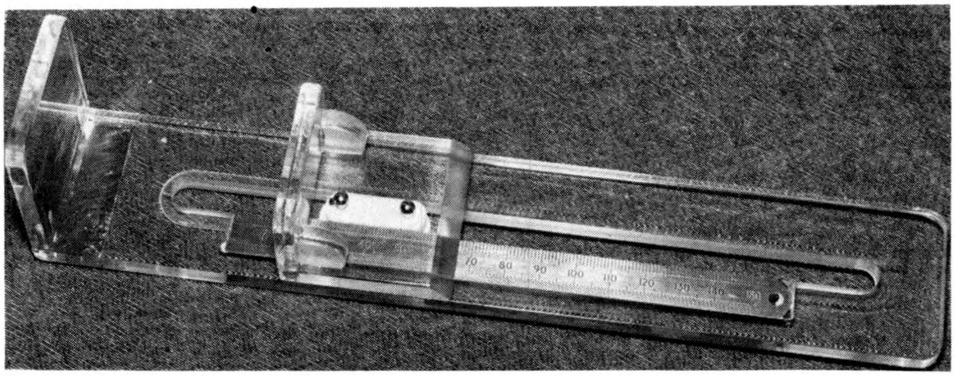

Fig. 1 *The neonatal foot length gauge.*

15 cm and reads to the nearest 0·5 mm. The instrument is small enough to be introduced through the porthole of an incubator within which it is easily manipulated.

The baby's left foot is held in the examiner's left hand and the gauge is held in his right. The heel is placed against the platform and the head of the first metatarsal and medial aspect of the heel are aligned parallel with the edge of the instrument. The index finger of the examiner's right hand manoeuvres the sliding bar until it just touches the tip of the big toe (Fig. 2). The instrument is withdrawn and the scale is read.

Observer error of the method. The left foot of one baby was measured by one of us (D.K.J.) on 10 occasions within 30 minutes. The result (mean ± SD) was 7·62 ± 0·08 cm; the coefficient of variation was 1·05%. The same baby's foot was measured once by 10 different examiners (nursing and medical staff of the special care baby unit). The result (mean ± SD) was 7·56 ± 0·11; the coefficient of variation was 1·46%.

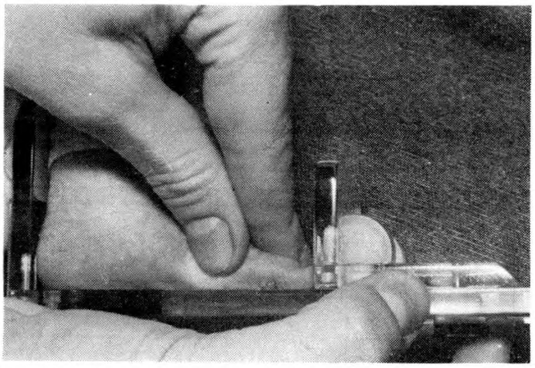

Fig. 2 *The neonatal foot length gauge.*

Measurements were made of foot length (left), OFC, crown-rump, and crown-heel length (CHL) in 123 singleton babies (M:F 59:64), 26–42 weeks' gestation, and of known birthweights. Measurements were made between 12 hours and 5 days. Serial observations previously made suggested that there was no significant change in foot or body length during the first 5 days of life. OFC measurements were made with a glass-fibre tape measure, and body length was measured with the Cardiff neonatometer (Davies and Holding, 1972). Gestational age of each baby was calculated from the first day of the mother's last menstrual period. If this was unknown, clinical examination of the newborn and/or radiological assessment of bone age was used to determine gestational age (Russell, 1969). 66 babies were of weights appropriate for gestational age (AGA) according to the birthweight centile chart of Milner and Richards (1974). 57 babies were < 10th centile for gestational age and were termed light-for-dates (LFD).

Results

In the 94 term (37–42 weeks) AGA and LFD babies birthweight was the index of body size that had the greatest scatter of the results about the mean (coefficient of variation = 12·0 and 11·9% respectively), whereas the coefficients of variation of foot length, OFC, and body length were smaller (3·5–8·5%) (Table 1). Nevertheless, in babies of different maturity there was a wide range of foot lengths at each gestational age and there was a considerable overlap between foot lengths at different gestational ages (Fig. 3).

For each index of body size the mean result in LFD term babies was compared with the corresponding result in AGA term babies and the percentage reduction was calculated. LFD babies

were 30·9% lighter than AGA babies. However, there was only a modest reduction (4·2–8·8%) of the mean foot length, body length, and OFC in LFD babies compared with AGA babies (Table 1).

A positive linear correlation between foot length and the other indices of body size was observed in AGA and LFD babies of all gestational ages (Table 2). However, the foot lengths of the 23 premature babies (< 37 weeks) showed an especially high degree of correlation with birthweight (r = 0·95) and crown-heel length (r = 0·96), and the 95% confidence limits of the regression lines were ± 327 g and ± 2·3 cm respectively (Figs 4 and 5).

Discussion

Ill newborn babies nursed in incubators and receiving intensive care are generally inaccessible for measurements of bodyweight and CHL. Such babies are usually premature and, as well as requiring intravenous fluids, are potential recipients of a variety of drugs including antibiotics, digoxin, and alkalising agents, the dosages of which are calculated according to bodyweights or surface areas. We have shown that birthweights and CHL of premature babies can be estimated from measuring the foot lengths and such measurements can be made simply, rapidly, and safely in spite of the encumbrance of the incubator and intensive care equipment. In those babies who are so ill at birth that measurements of weights and body lengths are not possible, the measurement of foot length allows fluid requirements and drug dosages to be calculated.

In term babies foot lengths, like body lengths, and OFC had relatively small scatter of results about the mean compared with birthweights. Markowski and Lawler (1977) suggested that foot length could be used to predict the gestational age of very premature aborted fetuses. However, in this study the range of foot lengths at different gestational ages was so wide as to preclude the accurate estimation of maturity.

It is conventional teaching that LFD babies tend to be long and to have large heads in relation to their birthweights. Our findings reinforce this and suggest that in most cases of intrauterine growth retardation foot length is also spared at the expense of bodyweight. Járai *et al.* (1977) drew attention to the heterogenecity of LFD babies and demonstrated that those who suffer from hypoglycaemia tend to have a greater reduction in birthweight relative to CHL compared with normoglycaemic LFD babies. The measurement of foot length may prove to be a valuable adjunct to other anthropometric measurements in the classification of LFD babies; it may be the only measurement that can be conveniently made in ill babies nursed in incubators.

We are grateful for the help of Mr S. Carlisle and the Department of Medical Physics who constructed the neonatal foot gauge.

Short reports

Mycoplasma hominis

A cause of neonatal meningitis

M. GEWITZ, R. DINWIDDIE, L. REES, O. VOLIKAS, T. YUILLE, B. O'CONNELL, AND W. C. MARSHALL

Department of Microbiology and the Respiratory Unit, The Hospital for Sick Children, Great Ormond Street, London

SUMMARY Two cases of *Mycoplasma hominis* meningitis in the newborn are described. These infants demonstrate the need to consider *M. hominis* as a cause of neonatal meningitis, especially if the Gram stain is negative, conventional cultures yield no growth, and there is a history of maternal infection. CSF cultures on appropriate medium can quickly confirm the diagnosis.

Neonatal central nervous system (CNS) infection due to *Mycoplasma hominis* has rarely been reported, despite the frequency with which it colonises the newborn (Klein *et al.*, 1969). A review by Remington and Klein (1976) described only 2 patients, and another case was recently reported (Siber *et al.*, 1977). This paper reports 2 more cases and demonstrates the significance of *M. hominis* in the aetiology of neonatal CNS infection, especially when the initial culture is negative.

Case reports

Case 1. The 1·74 kg baby girl of a 37-year-old gravida 5 para 1 mother was delivered at 33 weeks' gestation via forceps after membranes had been ruptured for 5 days. At delivery the mother's temperature was 38·3°C (oral) and although treated with ampicillin her fever persisted for 6 days. The baby was bottle fed and did well for the first 5 days of life but then developed fever (38·8°C rectally). Skin, blood, and suprapubic urine cultures were performed but no antibiotics were given. These cultures were sterile but on the 7th day the WBC was 36 000/mm^3 ($36 \times 10^9/l$) (79% neutrophils and 17% lymphocytes). Fever persisted and lumbar puncture was performed on the 8th day (Table 1). This confirmed the diagnosis of meningitis. IV ampicillin (200 mg/kg per day) and chloramphenicol (50 mg/kg per day) were started, and 1 mg intrathecal gentamicin was also administered. Generalised seizures developed and phenobarbitone was given. On the 9th day (Table 1) 0·5 mg gentamicin was instilled into the left lateral ventricle. At this time a growth of *Mycoplasma* was obtained from the mother's blood culture and the infant was started on IV tetracycline (20 mg/kg per day). Ampicillin was stopped but 2 further doses of intraventricular gentamicin were given. On the 15th day of life (10th day of illness) *Mycoplasma* was isolated from the

CSF obtained at the original lumbar puncture. All *Mycoplasma* isolated were later identified as *M. hominis*. Drug sensitivities for the organism are listed in Table 2. Subsequent antibiotic treatment consisted of IV chloramphenicol and tetracycline for a total of 21 days of each drug. There was continued improvement in the CSF and there were no more convulsions after the 10th day of treatment. The baby was discharged on the 40th day of life when neurological examination was entirely normal; follow-up at 9 months showed development to be normal with no evidence of residual neurological dysfunction.

Case 2. A baby girl born at term after an uncomplicated pregnancy and delivery. Birthweight was 4·02 kg. Nine days after birth the mother developed a febrile illness associated with a thick vaginal discharge. She was started on oral ampicillin and septrin, and continued to breast feed the infant who remained well. At 15 days the child became irritable and developed a fever of 38·0°C (rectal). Three days later she developed 'head retractions' and vomiting. She was admitted to hospital at 21 days; she was feeding poorly, febrile, irritable, and had generalised hypotonia. A lumbar puncture confirmed the diagnosis of meningitis (Table 2). Blood and urine cultures were sterile. Peripheral WBC was 26 100/mm^3 ($26·1 \times 10^9$/l) (93% neutrophils). She was started on gentamicin (4 mg/kg per day) and cloxacillin (62·5 mg/kg per day) together with phenobarbitone and hydrocortisone. There was a transient improvement but she deteriorated 2 days later. Antibiotics were changed to ampicillin (250 mg/kg per day) and cloxacillin (250 mg/kg per day). Again transient improvement was noted although CSF showed a persistent heavy pleocytosis. Bacteriological culture of CSF, however, remained sterile. At age 32 days the child deteriorated once again with seizures, pyrexia, and vomiting. She was transferred to The Hospital for Sick Children where repeat lumbar puncture was performed and CSF cultured for *Mycoplasma*. Gentamicin (6 mg/kg per day) was again given and cloxacillin was stopped in favour of chloramphenicol (25 mg/kg per day). Seizures were controlled with phenytoin (7 mg/kg per day) and rectal paraldehyde. Three days later *Mycoplasma* was identified from the CSF and later shown to be *M. hominis*. Oxytetracycline was started (20 mg/kg per day) and chloramphenicol stopped when drug sensitivities were obtained for the organism (Table 3). During the next 2 weeks there was clinical improvement with fewer seizures, good weight gain, and persistent improvement in the CSF. Antibiotics were stopped after 21 days of treatment with gentamicin and tetracycline, the latter being given orally for the last 10 days. At discharge the baby, aged 9 weeks, had normal reflexes, good tone, and was beginning to smile. She remained on anticonvulsant treatment in tapering dosage. Follow-up at age 10 months showed that she was developmentally normal for age, but had clinical evidence of a mild right-sided hemiplegia.

Table 3 *Sensitivities of two strains of Mycoplasma hominis to antimicrobial drugs*

Discussion

M. hominis is known to be a cause of paediatric illness and puerperal sepsis (Stokes, 1955; Klein *et al.*, 1969). The 2 cases described also demonstrate its role in neonatal CNS infection. In Case 1 the organism was not isolated until the 15th day of illness when pinpoint colonies were seen on Columbia blood agar (oxoid) and were grown within 48 hours of transfer to PPLO media (Difco nutrient base with 20% horse serum, 6·6% yeast extract, and ampicillin 1000 units/ml). In Case 2, pinpoint colonies showed the typical 'fried egg' morphology that was described by Siber *et al.* (1977). Growth may also be enhanced by incubation with 10% carbon dioxide

Table 2 *CSF results in Case 2*

Conversions as in footnote to Table 1. NR = Not recorded or nitrogen, but neither method was used in these cases. Both patients probably acquired the infection from their mothers and the meningitis was treated in the conventional way once the diagnosis was confirmed but neither responded despite several changes of antibiotics. It was only after identification of *M. hominis* and the institution of appropriate treatment based on the sensitivities of the organism that there was clinical improvement.

We thank Professor Hurley and Dr de Luvois of Queen Charlotte's Hospital, London for bacteriological identification in Case 1, the staff of the Mycoplasma Reference Laboratory for classification of the organisms, Miss J. Robinson and Miss P. Redmond for clerical help.

A clinical comparison of beclomethasone dipropionate delivered by pressurised aerosol and as a powder from a rotahaler

A. T. EDMUNDS, SHEILA McKENZIE, MARIAN TOOLEY, AND S. GODFREY

Department of Paediatrics and Neonatal Medicine, Hammersmith Hospital, Du Cane Road, London W12 0HS

SUMMARY 14 children with severe asthma were studied for 2 months in a double-blind cross-over trial to compare the efficacy of beclomethasone dipropionate delivered as an aerosol and as a powder from a rotahaler.* Inhalation via the aerosol was satisfactory in 13 patients, each of whom used the rotahaler correctly. Younger children preferred to use the rotahaler. Comparison of daily symptoms, twice daily peak expiratory flow rate (PEFR), and use of salbutamol during the 2 months of the trial showed that control of asthma was equally good, irrespective of the device used to deliver active beclomethasone.

There have been many studies demonstrating that beclomethasone dipropionate aerosol is safe and effective in the long-term management of severe childhood asthma (Morrow Brown and Storey, 1973; Godfrey and König, 1974; Lovera *et al.*, 1976). However, some children have difficulty using pressurised aerosols correctly, and consequently they have been denied the benefit of this form of treatment. Recently beclomethasone dipropionate has become available in powder form mixed with a lactose base. It is dispensed in capsules which are used in a rotahaler* (Hallworth, 1977). This device requires less co-ordination for effective use as the patient has only to breathe through it to inhale the powder. We have conducted a 2-month double-blind randomised cross-over trial to determine whether beclomethasone dipropionate dispensed in this way is as effective in controlling symptoms of asthma as the usual preparation delivered as a metred dose from a pressurised aerosol. We also tried to find out if there were any problems associated with the use of the rotahaler in paediatric outpatient practice.

Patients and methods

Seven boys and 7 girls (mean age 9·7 years, range 4·8–15·1 years) were studied. They were all asthmatic and had previously been judged on clinical grounds to require treatment with beclomethasone. Before the trial they had been using beclomethasone regularly for a mean period of 1 year 10 months (range 0–5 years 5 months). 11 of them had failed to respond satisfactorily to treatment with sodium cromoglycate and one had failed to respond to treatment with regular theophylline. Two had previously been treated with alternate day oral prednisolone and had subsequently been weaned off this on to aerosol beclomethasone dipropionate. Three patients had required short courses of oral prednisolone during the previous year.

---

*Allen and Hanbury's Research Division.

At the start of the trial all the patients were taught how to use both the aerosol and the rotahaler. At the end of the month each child was asked to demonstrate the use of both devices. He/she was given a score out of 10 for use of the aerosol. Droplet escape from nose or mouth, timing of aerosol release during inspiration, and size of breath taken (tidal or full vital capacity) were scored. It was noted whether the child was able to assemble the rotahaler correctly with the capsule in place, whether the powder fell on the floor, and whether he/she made an inspiratory effort great enough to inhale all the powder.

Throughout the trial the patients took two puffs of aerosol 4 times a day and powder from one capsule in the rotahaler 4 times a day. Each month one device contained active drug and the other an appropriate placebo. The order in which the patients received the drugs was randomly assigned by the hospital pharmacist and was not disclosed to the patients or the physicians until the trial was completed. All patients were given a salbutamol aerosol in addition to the beclomethasone to use as necessary for cough or wheeze. During the trial the patients recorded their symptoms each day in a diary card (Connolly and Godfrey, 1970). They also recorded peak expiratory flow rate (PEFR) every morning and evening. This was measured as the best of 3 attempts using a calibrated peak flow gauge (Airmed Ltd). The amount of salbutamol used to treat intermittent symptoms was also noted. Comparison of the results in the two treatment periods was made using paired *t* tests.

Results

Use of inhalation devices. All children were able to use the rotahaler correctly and 13 achieved mean scores of 8 or more for aerosol inhalation technique. Two had not used an aerosol before the trial. One of these had a mean score of 5 for inhalation technique. The Table shows that younger children preferred to use the rotahaler while older ones preferred the aerosol. Although the figures are too few for statistical analysis there did not appear to be any relationship between the length of time of previous beclomethasone treatment and preference for device.

Table *Age of patients, time of previous experience with aerosol, and preferred device (aerosol or rotahaler)*

Age of patient (years)	*Previous duration of aerosol treatment (years)*	*Preferred device*
15·1	1·3	Aerosol
13·8	2·3	No preference
13·7	0·0	No preference
12·8	1·2	No preference
11·9	1·3	No preference
10·7	5·4	Aerosol
10·1	1·3	Aerosol
9·8	2·9	Aerosol
7·3	2·9	No preference
7·1	1·1	Rotahaler
6·9	0·0	No preference
6·0	2·0	Rotahaler
5·8	2·8	Aerosol
4·9	1·1	Rotahaler

Response to treatment. Symptom scores, number of symptom-free days, morning and evening PEFR results, and the amount of salbutamol used were recorded for each month of the trial. The mean symptom score was significantly lower during the month of treatment with active aerosol and placebo powder (P = 0·04), but there were no significant differences between the two periods for any of the other recorded parameters. The child who scored only 5 out of 10 for aerosol inhalation technique was as well in the month that he was taking aerosol as in the month that he was using the rotahaler. Of 8 patients who stated a preference for one type of device only 2 were controlled better during the month they were using that device.

Discussion

This trial has shown that beclomethasone dipropionate delivered from a rotahaler was as effective as that delivered by pressurised aerosol in controlling the symptoms of this selected group of asthmatic children. Most of the patients had been using the aerosol for some time and all but one were given a mean score of at least 8 for their aerosol inhalation technique. Preference for a particular type of device was not related to symptom score or PEFR recorded during the month of its use for active drug. However, the 3 patients who preferred to use the rotahaler were among the younger children in the trial. It is probable that the rotahaler would prove more effective than an aerosol for young children who have difficulty using pressurised aerosols. Provided inhalation is continued until all the powder from each capsule is used, there is far less chance that it will be delivered incorrectly. All our patients were able to use the device without difficulty.

It is concluded that beclomethasone powder delivered from a rotahaler is a useful addition to the therapeutic armoury for the management of severe asthma in childhood.

Cefuroxime plasma and CSF levels in children with meningitis

J. A. KUZEMKO AND S. R. WALKER

Paediatric Department, Peterborough District Hospital, and Glaxo Research Limited, Clinical Division, Greenford, Middlesex

SUMMARY Cefuroxime (25 mg/kg) given intravenously every four hours to 7 children with bacterial meningitis resulted in satisfactory therapeutic blood and CSF levels. All children made a full recovery and side effects were absent.

Bacterial meningitis in children carries a 10–15% mortality rate and there can be significant neurological damage in children who recover (Goldacre, 1977). The success of any antibiotic in the treatment of this disease depends on its antibacterial properties and the concentration that remains in the blood and CSF after systemic administration. Unfortunately, during the last few years, sulphonamide-resistant meningcocci have emerged (Lambert, 1974), *Haemophilus influenzae* is now sometimes resistant to ampicillin because of β-lactamase production, and meningitis due to chloramphanicol-resistant *H. influenzae* has recently been reported (Kinmonth *et al.*, 1978). Therefore, triple treatment with a sulphonamide, ampicillin, and chloramphenicol is often used before the causative organism is known. Cefuroxime, unlike the other three agents, is highly active against all the organisms that commonly cause meningitis—namely *Neisseria meningitidis*, *H. influenzae*, and *Streptococcus pneumoniae* (O'Callaghan *et al.*, 1976). It was felt appropriate, therefore, to determine blood and CSF levels of cefuroxime in children with meningitis before this antibiotic was considered as an alternative treatment.

Patients, methods, and results

The treatment currently used at this hospital for children with meningitis consists of ampicillin (25 mg/kg), chloramphenicol (15 mg/kg), and sulphadimidine (25 mg/kg), by IV infusion every four hours for a period of up to 5 days. Treatment is modified depending on the sensitivity of the organism to these agents, and then it is continued orally for an additional period of 5 days.

Cefuroxime (25 mg/kg) was given intravenously by a 20-minute infusion every four hours to 7 children (6 boys; age range, 1½–6 years) for periods of between one and 5 days in addition to the above treatment. The organism responsible for the meningitis in 3 children was *N. meningitidis* (all resistant to sulphadimidine), and in the other 4 it was *H. influenzae*. Sensitivity testing showed that all the isolated organisms were highly sensitive to cefuroxime. Blood samples were taken twice during treatment and plasma levels of cefuroxime were determined between 30 and 90 min and 4 hours after injection. CSF levels of cefuroxime were measured in 3 patients in whom lumbar punctures were clinically indicated; one child with CSF pressure had lumbar punctures performed 2 hours after a cefuroxime injection on 4 consecutive days. All samples were analysed by a high-pressure liquid chromatography method which enabled cefuroxime to be determined in the presence of other drugs.

Plasma levels of cefuroxime (Figure) determined at between 30 and 90 min and 4 hours after IV infusion

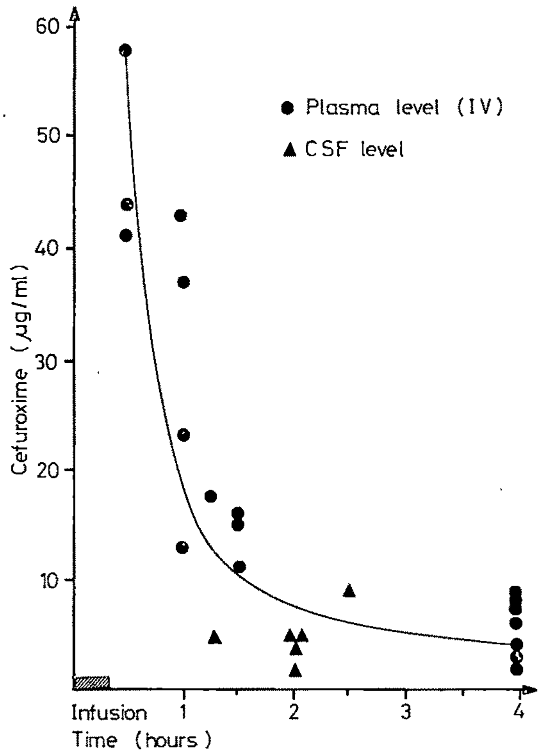

Figure *Plasma levels of cefuroxime in children with meningitis.*

showed that adequate blood levels were obtained and maintained throughout the treatment period. In 3 children the concentration of cefuroxime in CSF was determined and found to be between 1·5 and 9 µg/ml.

Comment

Satisfactory therapeutic blood and CSF levels of cefuroxime are obtained in children with bacterial meningitis, if a dose of 25 mg/kg is given by IV infusion every 4 hours. CSF levels were several times higher than the MICs for *N. meningitidis* (0·025 µg/ml) and *H. influenzae* (0·5 µg/ml). No toxic side effect was noted and all the children made a good recovery. Although one patient was treated successfully with cefuroxime alone after the first day on triple therapy, further clinical studies with cefuroxime are needed to determine whether this new cephalosporin should become a first-line treatment of bacterial meningitis.

We thank Mr John Ayrton of Glaxo Research Limited for the cefuroxime analyses.

Idiopathic hypoparathyroidism with extrapyramidal and myopathic features

R. O. WALTERS
The Hospital for Sick Children, Great Ormond Street, London

SUMMARY A case of idiopathic hypoparathyroidism and basal ganglia calcification with extrapyramidal motor and myopathic features is described. The extrapyramidal motor and myopathic features disappeared when normocalcaemia was restored with treatment, suggesting that they resulted from hypocalcaemia.

Idiopathic hypoparathyroidism is an uncommon disease of childhood in which the typical neuromuscular disorders are tetany, fits, and mental retardation. Extrapyramidal and myopathic features have only rarely been described.

Case report

A 12-year-old boy presented with a 2-year history of sudden episodes of generalised tingling, followed immediately by uncontrollable muscle spasms with his limbs assuming bizarre postures, occasionally resulting in his falling to the ground. The episodes occurred 2 or 3 times a week and appeared to be more severe and more frequent after exercise.

He was the only child of healthy unrelated parents. His early growth and development had been normal. When aged 3, he was noted to have an abnormal gait attributed to coxa vara; there was some improvement with treatment, but he continued at times to walk stiffly on tiptoe. His parents felt that for 2 years he had lacked drive, but his school performance had remained satisfactory.

On examination, he was an intelligent boy of normal stature with no dysmorphic features. He had a mask-like facies, exhibited a poverty of movement, and walked with a slow stiff gait; he had strikingly increased muscle tone in all limbs without muscle wasting, tenderness, or weakness; deep tendon reflexes were diminished; he had difficulty in performing rapid repetitive movements, but he was not ataxic and had no sensory deficit. Chvostek's sign was positive and he exhibited chronic carpo-pedal spasm.

Investigations. Plasma calcium 1·37–1·83 mmol/l (5·48–7·32 mg/100 ml), phosphate 2·49–2·87 mmol/l (7·7–8·9 mg/100 ml), magnesium 0·66–0·70 mmol/l (1·6–1·7 mg/100 ml), albumin 44–49 g/l (4·4–4·9 g/100 ml), alkaline phosphatase 183–272 IU/l; urine calcium excretion 0·15 mmol/24 h (6 mg/24 h), phosphate excretion 10·21 mmol/24 h (0·32 g/24 h). Serum parathormone (PTH) 50 pg/ml (normal 250–680), serum 25 hydroxycholecalciferol 27·5 μg/ml (normal 5–30). Plasma creatine kinase (CPK) 13·0 μmol/ml per hour at 37°C (normal 0·25–3·6), alanine aminotransferase 23 IU/l, aspartate aminotransferase 22 IU/l. An Ellsworth Howard test showed a phosphaturic response to PTH. ECG showed a prolonged QTc of 0·49 seconds. An *x*-ray of skull was normal, but computerised axial tomography (CAT) showed dense calcification in both lentiform and caudate nuclei and in both cerebral hemispheres (Figure). EEG showed an excess of large amplitude slow activity without localising or paroxysmal features.

Blood count, ESR, blood urea and glucose, plasma electrolytes, creatinine, bilirubin, immunoglobulins, cortisol and ACTH, serum thyroxine and TSH, urine analysis, urine amino-acids, and faecal fat excretion were normal; no autoantibodies were detected.

A diagnosis of idiopathic hypoparathyroidism was made and treatment was started with dihydrotachysterol (DHT), with calcium and magnesium supplements, and aluminium hydroxide. There was a rapid response to treatment with complete relief of symptoms and signs when the plasma calcium rose above 1·9 mmol/l (7·6 mg/100 ml). Maintenance therapy with DHT 0·5 mg daily continues and the patient remains well.

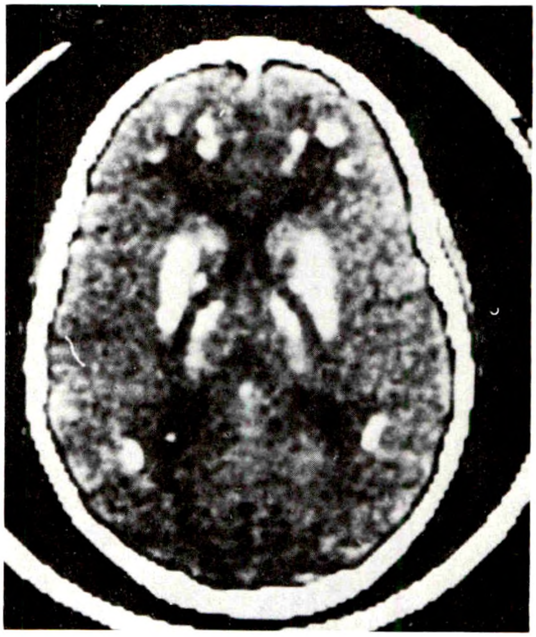

Figure *CAT showing dense intracranial calcification which was not apparent on skull x-ray.*

Discussion

The patient had idiopathic hypoparathyroidism and basal ganglia calcification demonstrated by CAT. He exhibited extrapyramidal motor manifestations, in part related to exercise, which disappeared when normocalcaemia was restored. He also exhibited increased CPK activity to a level associated with myopathy which returned to normal when normocalcaemia was restored. While basal ganglia calcification will be seen more easily in the future by CAT, and therefore may be found more often in idiopathic hypoparathyroidism in childhood, extrapyramidal motor manifestations and raised CPK activity are both rare and do not appear to have been described previously in association with this condition.

Muenter and Whisnant (1968) reviewed the association between extrapyramidal motor manifestations and basal ganglia calcification, and found that the neurological deficit was usually reversible when the patients with hypoparathyroidism were treated.

Tabaee-Zadeh *et al.* (1972) reported a patient with paroxysmal kinesogenic choreoathetosis and basal ganglia calcification due to idiopathic hypoparathyroidism, in whom the extrapyramidal motor features improved when normocalcaemia was restored. They suggested that the movement disorder might be due to a direct effect of hypocalcaemia on already damaged neurones.

Hower *et al.* (1974) described a child with myopathy and idiopathic hypoparathyroidism with increased CPK activity which returned to normal with treatment. They suggested that hypocalcaemia led to lowered cell membrane potentials resulting in increased cell membrane permeability allowing the escape of cytoplasmic proteins.

The findings in this patient suggest that the extrapyramidal motor features were not due directly to the basal ganglia calcification, but that both they and the increased CPK activity resulted from the effects of hypocalcaemia on cell membrane potentials of neurones and muscle.

I am grateful to Dr D. B. Grant for advice and for permission to describe a patient under his care, and to Dr R. D. Hoare for the CAT scan.

Half life of theophylline in the preterm baby with apnoeic attacks

D. M. KING, A. F. HEELEY, AND J. A. KUZEMKO

Departments of Biochemistry and Paediatrics, District Hospital, Peterborough

SUMMARY Plasma theophylline levels were measured by an enzyme immunoassay method in 6 preterm babies. The method gave accurate and rapid results. The study showed a considerably prolonged half life of an oral preparation.

Xanthine derivatives have become established as a method of treatment of recurrent apnoeic attacks in the preterm baby (Lucey, 1975). However, because of the interpatient variation and prolonged half-life of theophylline in such babies (Giacoia *et al.*, 1976), it is essential that plasma levels be estimated frequently so that adequate doses of the drug can be maintained and serious side effects avoided.

We used an enzyme immunoassay method (EMIT, Syva) for determining plasma theophylline levels on as little as 10 μl plasma. It was known that plasma concentrations measured by either high pressure liquid chromatography or EMIT showed excellent agreement (Chang and Bastiani, 1977).

Patients and methods

Six preterm babies were studied. Details of gestation periods and birthweights are given in the Table. After one attack of apnoea lasting at least 25 seconds, a single oral theophylline preparation was given by a nasogastric tube (theophylline BP as sodium glyconate salt 5 mg/kg). Plasma theophylline levels (μg/ml) were measured at 0, 2, 4, 8, 12, 24, and 48 hours. If a baby had a second attack of apnoea during the period he was withdrawn from the study.

Plasma theophylline levels were estimated by enzyme immunoassay using the EMIT-aad kit

Table *Details of the 6 preterm babies*

Case	*Age (days)*	*Birthweight (g)*	*Gestation (weeks)*	*Theophylline half life (hours)*
1	3	1370	31	35
2	5	2500	36	33
3	11	1400	31	25
4	2	1030	28	64
5	3	2240	37	32
6	12	1950	34	24

(Syva). Volumes of 10 μl plasma were pipetted into microsample cups and thereafter dilutions, reagent additions, and reaction kinetics were performed on the Gilford 3500 analyser in accordance with the manufacturer's instructions for this assay. Under these conditions, neonatal plasma, to which known amounts of theophylline were added, gave coefficients of variation between expected and measured concentrations ranging from 6·5% at 2 μg/ml to 5·5% at 10 μg/ml; values which are compatible with the reported between-run precision of the assay itself.

Results

Peak plasma levels occurred between 4 and 8 hours after the single oral administration of theophylline. The slope of the log of the plasma concentration in the postabsorptive phase plotted against time was used to determine the half-life of the drug. The theophylline half-life for each baby is shown in the Table. The range was 24–64 hours.

Comment

The enzyme immunoassay method for measuring plasma theophylline levels by using microsamples in this group of preterm babies was found to give accurate, reproducible, and rapid (within 10 min) results, thus allowing theophylline dosage to be regulated as often as is clinically indicated. The study showed the prolonged half life of an oral theophylline preparation and the wide interpatient and within-patient variations.

EMIT reagents were kindly donated by Syva Corp. and the 3500 analyser lent for laboratory evaluation by Gilford Instruments Ltd. The oral theophylline was prepared by McCarthy's Pharmaceuticals.

Sodium valproate and pregnancy

Sir,
We were presented with a baby born to a mother taking sodium valproate who wished to breast feed. There are no data on breast milk levels of sodium valproate; it is presumed from collateral evidence that some of the drug would pass across from maternal serum into the milk. Studies in animals given modest doses of sodium valproate during pregnancy (30–90 mg/kg) showed no significant teratogenic effects. When a much higher dose was used (about 600 mg/kg) there was a dose-related increase in the rate of intrauterine death and major fetal abnormalities, most of which involved the kidneys or the lower lumbar spine (Whittle, 1976).

Information on the outcome of the pregnancies where sodium valproate has been taken as the main anticonvulsant is very scanty; in most reports two or more drugs have been used or, in the case of an abnormality, the family history has suggested a strong genetic element (W. Reckitt-Labaz, 1978, personal communication).

Case 1, a 22-year-old primipara, was epileptic and changed to sodium valproate in November 1975. She was well controlled taking 1600 mg/day in divided doses. She had had irregular periods and did not realise that she was pregnant until she was about 14 weeks. She consequently booked at the hospital clinic at about 18 weeks. Her anticonvulsant drug was not changed.

She was admitted in labour at term in July 1978 and delivered a healthy boy weighing 3010 g; Apgar score was 9 at one minute, and no abnormalities were observed. The baby breast fed well and was discharged home on the 6th day, slightly under his birthweight. Mother and baby were seen at 29 days after delivery. The baby was still breast feeding well, gaining weight, and beginning to smile.

The sodium valproate level was measured in the mother's serum, as shown in the Figure. The level fell slightly at term without any change in the oral dose and then rose to the previous level by 29 days. The valproate level in the serum of the neonate was of the same order as that of the mother's at delivery, but fell to insignificant levels by 5 days and was undetectable at 29 days (Figure). The mean level of valproate in breast milk at 5 days was 50 mmol/l; it had fallen to 21 mmol/l by 29 days.

The neonatal valproate level indicates that valproate crosses the placenta freely and maternal serum levels will reflect fetal serum levels. Sodium valproate crosses through from serum into breast milk and will be found at a level between 5 and 10% of that in the mother's serum. The absorption of valproate from breast milk by the neonate appears to be insignificant. In this instance there was no evidence of any abnormality associated with the use of this drug.

It may be concluded that breast feeding while on therapeutic doses of sodium valproate is safe and will not result in detectable neonatal blood levels. Nevertheless, in early pregnancy it must still be prescribed with caution until there is evidence of its safety.

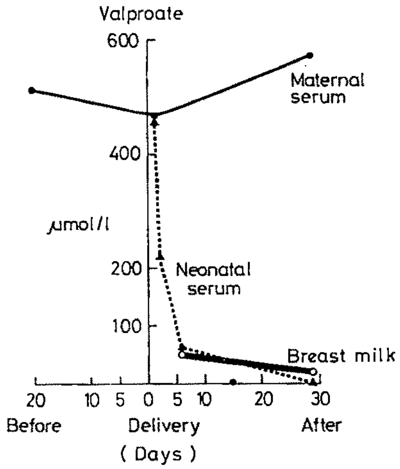

Figure *Maternal serum and breast milk levels of sodium valproate, note marked fall in neonatal serum levels.*

Breast feeding and smoking

Sir,
Success at breast feeding has been related to social class (Martin, 1978) and the age at which the mother finished full-time education (Last, 1978; Martin, 1978; Pursall *et al.*, 1978). This study was aimed at determining the prevalence of breast feeding in Cambridge, after delivery and at 3 months. The influence of smoking by mothers was also examined. Smoking by the mother has been shown to have adverse effects on the fetus (Butler *et al.*, 1972) and smoking by either parent an adverse effect on the health of the infant (Leeder *et al.*, 1976), but its effects on lactation do not appear to have been investigated.

330 women delivered consecutively at the maternity hospital in Cambridge in 1978 were questioned after delivery and again at 3 months. The overall prevalence of breast feeding after delivery was 82% and at 3 months' postpartum it was 46%. Initial choice of infant feeding was influenced by social class, with 86% of women from the nonmanual classes starting by breast feeding compared with 76% of manual class women.

The Table compares the prevalence of bottle feeding from delivery, bottle feeding at 3 months by those who began by breast feeding, and breast feeding at 3 months in smokers and nonsmokers. Smokers were less likely to attempt breast feeding than nonsmokers, and this achieves statistical significance in the group overall ($\chi^2 = 6\cdot752$, $P<0\cdot01$) and the manual classes ($\chi^2 = 6\cdot389$, $P<0\cdot02$). Furthermore mothers who smoked and began by breast feeding were more likely to have changed to bottle feeding by 3 months than mothers who did not smoke, and this achieves statistical significance in the nonmanual classes ($\chi^2 = 3\cdot894$, $P<0\cdot05$). Comparison of the mothers who began by bottle feeding with those who were breast feeding at 3 months shows that there were more smokers among the bottle feeders in the group overall ($\chi^2 = 15\cdot494$, $P<0\cdot001$) and in both the nonmanual ($\chi^2 = 4\cdot657$, $P<0\cdot05$) and manual classes ($\chi^2 = 5\cdot26$, $P<0\cdot05$).

Table *Maternal smoking and infant feeding*

	Social class	*Total*	*Artificial feeding*		*Changed to artificial feeding by 3 months*		*Breast feeding at 3 months*	
			No.	*%*	*No.*	*%*	*No.*	*%*
Smokers	Nonmanual	18	5	28	6	33	7	39
	Manual	26	11	42	11	42	4	15
Non-smokers	Nonmanual	117	14	12	28	24	75	64
	Manual	69	12	17	37	54	20	29

There were, as might be expected (Capell, 1978), more (27%) smokers among the manual class mothers than among the nonmanual women (13%). The reasons for smokers being less inclined to breast feed and less likely to persist with breast feeding cannot be ascertained from this study. Smoking was not associated with any particular reason for giving up breast feeding. Nevertheless it appears that smoking by the mother is yet another factor which may influence the prevalence of breast feeding.

Circulating immune complexes in mucocutaneous lymph-node syndrome (Kawasaki disease)

Sir,
The clinical features of mucocutaneous lymph-node syndrome (MLNS) are well established (Kawasaki *et al.*, 1974), but the aetiology is unknown. Fossard and Thompson (1977) described a Japanese child living in England in whom raised levels of circulating immune complexes by the platelet agglutination test were found early in the disease. Total haemolytic complement and C_4 were depressed although C_3 levels were normal.

Recently we have been able to confirm the abnormal immune complex findings in a 9-month-old Caucasian girl with MLNS. She presented with fever, rash, and stomatitis. After 3 days she became irritable and photophobic; the rash became confluent and prominent over the palms and soles. Lumbar puncture and CAT scan were normal, and she showed no response to several antibiotics (erythromycin, fucidin, flucloxacillin, or ampicillin). Two weeks after the onset of symptoms she was admitted to this hospital where she was noted to have an erythema multiforme-like rash, marked cervical lymphadenopathy, stomatitis, nonpurulent conjunctivitis, puffy feet, and tachycardia. The skin at the fingertips had started to desquamate. She was mildly anaemic and had a leucocytosis. IgE was 44 IU/ml (normal) and total haemolytic complement and C_3 levels were also normal (155 and 124% of normal human serum respectively). Immune complexes containing IgG were raised (41·5% inhibition of IgG latex agglutination (Levinsky and Soothill, 1977): normal subjects <20%). Her illness resolved without further treatment and she was well when she was discharged home on the 43rd day.

Many of the clinical features of this disorder—such as arthralgia, rash, and myocarditis with coronary artery vasculitic changes—could well be due to immune complex deposition. However, raised levels of soluble immune complexes have been described in a variety of diseases and it is difficult to decide whether they are the cause or the result of the disease. Isolation and characterisation of the complexes in patients with this disorder may help to establish the aetiology of this strange disease.

Thermometers and rectal perforations in the neonate

Sir,

The traumatic origin of many 'spontaneous' perforations of the alimentary canal is worthwhile emphasising (*Archives*, 1978, **53**, 824). Two similar patients were reported previously from Great Ormond Street (Young, 1965) and were described at the Royal Society of Medicine. In the discussion that followed an experienced paediatrician commented, 'This seems to explain the reason why I have intermittent bursts of infants with rectal bleeding as, on reflection, this seems to occur each time we have a new batch of nurses in the nursery'. The presumed cause of this bleeding was from mucosal tear caused by the passage of a thermometer to the rectum.

Perforation of the rectum by thermometers or tubes is more common than reports suggest. Stomach tubes can also be implicated as the cause of some of the 'spontaneous' perforations of that organ.

In an article (Young, 1965), the importance of instruction to nurses was emphasised: 'Instruction to nurses on the anatomy of the rectum must be clear, and to take a rectal temperature the thermometer should be inserted into the anal canal and then advanced at an angle of 30° backwards, not straight into the rectum parallel to the cot as one so often sees'.

In the editorial comment on Frank and Brown's paper (*Archives*, 1978, **53**, 824) your experienced paediatricians give no reasons for the perpetuation of the widespread practice of taking temperatures per rectum. Could we have the reasons for continuing this, or a clear statement that it does not have inherent merit and does have a small but definite risk?

Estimation of gestational age at birth—comparison of two methods

Sir,

The Short Report by Serfontein and Jaroszwicz (*Archives*, 1978, **53**, 509) in which the method of Robinson for estimating gestational age was compared with that of Dubowitz contains several errors in both methodology and inference.

After regressing the Robinson gestational age on that by the Dubowitz method they state that 'the 95% confidence interval for a single estimation of gestational age . . . is + 1 week'. (It is curious that this figure is only given to one significant figure whereas the slope of their regression line has 3 and the intercept 7). Confidence intervals derived from regression lines are smallest at the mean (of X) and increase as X gets further from the mean. It is not possible to give a single figure, in this case ± 1 week, for the 95% confidence limits for a single estimation of gestational age. Furthermore, their figure of ± 1 week looks surprisingly small, even assuming it refers to the confidence limits at the mean. In any case, since the objective was to see if Robinson's method could replace the Dubowitz method, the Dubowitz age should have been regressed on the Robinson age; that is, the regression should have been performed the other way round.

The authors state that the Robinson method compares 'very favourably' with the Dubowitz scoring system. This vague statement is presumably based on the observed correlation between the two sets of gestational ages of 0·85. A correlation of this magnitude means that one method explains less than three-quarters ($0\cdot85^2$) of the variability of the other, which in this context is not especially good. They then say that 'both (methods) were found to be accurate between the ages of 29 and 37 weeks', and it is stated that all the mothers were reasonably sure of the dates of their last menstrual periods. However, definitions of 'accurate' and 'reasonably sure' are not given, and no comparison is presented between the 'true' gestational ages and those calculated by either of the two methods under discussion, so that the assertion about accuracy is unsupported.

A final criticism, concerning the design of their investigation, is that it appears that each assessment was carried out by a different person. If this is so, any inherent differences between the two observers are confounded with differences between the two methods, so that the two effects cannot be separated and it is impossible to make a true comparison.

The question which the authors should be asking is 'Do the two methods give comparable results?' and the degree of comparability which is felt acceptable should be specified. If the answer is 'yes' then it would be reasonable to use the simpler Robinson method instead of the more complicated (but better validated) Dubowitz one. Correlation does not answer this question. We expect two measures of the same thing to be correlated; what we are really interested in is the difference between the gestational ages calculated by the two methods. The simplest approach is to calculate the mean and SD of the differences between the two ages. A paired *t* test can be used to test for any systematic difference between the two measures. A significant result looks likely in this case as most of the points in their figure are below the line of identity. From the SD a 95% confidence interval can be calculated. Alternatively, a regression of the Dubowitz age on the Robinson age could be carried out. Each age by the Dubowitz method could then be compared with its estimate, using the regression equation and the observed and estimated ages compared in the same way as before.

The authors have not established that the Robinson method is a good approximation to the Dubowitz system, and their assertions about the accuracy of the method are unsupported.

Drs Serfontein and Jaroszewicz comment:

We thank Mr Altman for his interest in our paper, although the points he has raised, some of which are valid, are really minor ones and in no way affect the essence of the study.

Regarding the design of the investigation, at the start of the study a trial assessment was made by both of us in which each used the same method of assessment of gestational age on the same infant and no significant differences were disclosed. For the actual study it was felt that the fact assessments were made by two different observers (one doing only the Robinson technique and the other only the Dubowitz method) would result in greater objectivity. Independence of observation was ensured by the results of one examiner not being made known to the other.

With the term 'reasonably sure' it is meant that these were Cape Coloured mothers who could state definite dates of their last normal menstrual periods, had no bleeding within one month of those dates, and had regular menstrual cycles of 28±2 days, the last period being normal in amount and duration. The first day of the last menstrual period (LMP) was used as the reference day and the expected date of delivery was calculated as 280 days (40 weeks) from that day.

Regarding the statistical model and analysis of our study we reiterate that the Robinson method for estimation of gestational age is only pertinent between 29 and 37 weeks' gestation and it is between these limits that we assessed its value against the Dubowitz method. For this reason a paired *t* test comparing the two methods is undesirable. Should one want to do so it would have to be by means of a 4-fold contingency table with age groupings according to both methods. In this way the same restrictions are imposed upon the Dubowitz method as upon the Robinson method. There is no significant difference between the two methods when compared in this manner.

With respect to the correlation, we should like to point out that a correlation of 0·85 significant at P 0·01 suggests that there is one in 100 chance that this correlation is due to chance factors, i.e. reasons other than that warranted by actual strength of data. What this correlation means is that 67% of a rating on one scale is predicted by the ratings on the other scale, which is very high agreement considering other variables that might also influence the ratio. From any statistical view point this magnitude of correlation, which is also not due to chance, is a high one.

We agree that a spuriously high positive relationship may exist because each infant was subjected to both methods of examination. However, we feel the magnitude of the correlation is strong enough to counter this point. Considering that both the Dubowitz and Robinson assessments are subject to error, a correlation of 0·85 is in fact a *very* good one. Good (positive) correlation means that low values obtained with the Robinson method would also be low with the Dubowitz method and vice versa. Further response to this part of Mr Altman's criticism is hampered by the usage of terms such as 'in this context' which we, for our own part, find vague.

Our statement that 'the 95% confidence interval for a single estimation of gestational age is ± one week' is incorrect. This was due to a misinterpretation on our part of the statistician's results. We should, however, like to point out that the standard error of estimate for the Robinson method when measured against the gestational age as determined by LMP is 1·37 weeks, whereas that for the Dubowitz method is 1·94 weeks.

For these reasons and given the magnitude of correlation with only a small chance factor associated with it, it would seem that the Robinson method is a highly suitable alternative to the Dubowitz method for gestational age between 29 and 37 weeks.

Oral rehydration in infantile diarrhoea

Sir,

Chatterjee *et al.* (*Archives*, 1978, **53**, 284) prefer a solution containing 50 mmol/l sodium for the oral treatment of children with diarrhoea, instead of the 90 mmol/l recommended by the World Health Organisation (1976). In their study of 39 children they found the two solutions were equally effective for rehydration, but that the solution with higher sodium concentration resulted in somewhat more periorbital oedema and hypernatraemia. This difference was not, however, statistically significant and the problems were not shown to have clinical importance. The investigators rehydrated the children using an intragastric drip.

We successfully treated a large number of children from 2 months of age upwards with the solution recommended by the WHO. We normally give the solution as a drink, when the children's thirst controls the amount they take in, and we have found no problems with salt overload. Only in the relatively few children given the solution by intragastric drip for specific reasons (most commonly stomatitis, prostration, or excessive vomiting), have we sometimes encountered periobital oedema among the children a few months old, but this did not appear to influence recovery.

We agree with the generally accepted practice that the oral solution should normally be given as a drink. This is not only pleasanter for the child, but it is the only method suitable for mass use in developing countries, where shortages of trained staff and equipment will generally be much greater than in the conditions of the study in the Calcutta Medical College Hospitals. This method also allows for the close collaboration of the mother in her child's treatment with its potential for health education; and evidently it may be safer.

The common problem in poor conditions with inexperienced mothers and lack of staff is not overhydration but that the child will be given insufficient fluid. In these conditions the solution of higher sodium content is more practical since the volumes needed are less. Additional free water is neither necessary nor recommended. In Mozambique the national policy (Melamed and Segall, 1978) is to use the solution recommended by the WHO.

Dr Chatterjee and co-workers comment:

We thank Dr Vinhas *et al.* for some very pertinent comments on our paper on oral rehydration in infantile diarrhoea. They treated a group of children with diarrhoea with the oral solution recommended by the WHO and did not have any significant problems of salt overload. Furthermore, they administered the fluid as a drink, except in a few cases where a nasogastric tube was used. We preferred the use of a nasogastric tube for the following reasons: (1) we studied only those children with moderate and severe dehydration; they were very sick and were not well enough to drink, and rapid rehydration was mandatory; (2) as this was a controlled clinical trial, use of a nasogastric tube was preferred to reduce the variability in fluid administration, and (3) aspiration of stomach before administration of fluid, particularly in infants who received loads of antidiarrhoeal medicines before admission, reduces the chance of vomiting. Vomiting is also less likely if the child sleeps while receiving the fluid through a nasogastric tube and is not disturbed to take the drink. We agree that for mass use, if rehydration can be started early, fluid given as a drink is the method of choice and the use of a nasogastric tube should be limited to severely dehydrated infants in cases where quick rehydration is necessary.

The question of salt overload needs a detailed analysis. Although Dr Vinhas *et al.* did not mention the severity of the dehydration, we assume that most of the children had milder dehydration as they were well enough to drink. Even so, while attempting adequate hydration in a few of the severe cases through a nasogastric tube with the solution recommended by the WHO, periorbital oedema occurred in some of them. According to Dr Vinhas, in children receiving the oral fluids by mouth, amelioration of thirst limits the intake. In our experience, however, this is not always so and on many occasions the children continued to drink excessive amounts and developed periorbital oedema. It is pertinent to mention that the estimated episodes of diarrhoea in Asia, Africa, and Latin America in 1975 is 348·2 millions in children aged under 2 years (Rohde and Northrup, 1976). Therefore, if hypernatraemia occurs even in one in a thousand, it will lead to a problem of salt overload in an enormous number of children. We strongly feel that a recommended oral fluid for mass use in the field where supervision is inadequate, should have a higher margin of safety and that the low sodium solution being equally effective should serve this purpose.

Prophylactic diazepam in febrile convulsions

Sir,

We read with interest the paper by Knudsen and Vestermark (*Archives*, 1978, **53**, 660) shedding some new light on an old controversy about preventing febrile convulsions (FC). The authors stated that: (1) continuous treatment with phenobarbitone had no advantage over intermittent diazepam; (2) the administration of diazepam was not optimal, so that 80% of children received it too late; (3) diazepam is safe, quickly absorbed, free from undesirable side effects, and, unlike phenobarbitone, is subject to little parental resistance; (4) diazepam may be an alternative prophylaxis of FC, but further controlled investigations are needed.

We performed such an investigation in 1973–75 and checked the results in 1977 (follow-up 18–52 months).

We suggested that parents, after the first FC, should give diazepam (0.6–0.8 mg/kg per 24 hours orally, in 3 doses) at the first sign of illness continuing to the 2nd day after complete recovery. In 1977 we interviewed the parents of 101 children recalled for control and checked all records of readmissions for a new FC or other illness. Of these, 90 had had febrile episodes after the first FC and met the criteria for intermittent prophylaxis: 48 received diazepam by the method and in the doses suggested, 42 did not. The FC recurrence rate in the 'bad compliance' group was 48%, in the 'good compliance' group it was 4% (Dianese and Faccioli, 1979).

The conditions for an effective intermittent prophylaxis of FC with diazepam must be to give the drug in sufficient dosage and to give it in time. Is this feasible? We asked each mother of 100 children (aged between 6 months and 6 years; 45 boys and 55 girls) if she was able to realise that her child was unwell at least 6 hours before the actual fever occurred. In 86% of cases the mother said she was. The symptoms are often trivial, personal, and not 'scientific' in nature, but they are useful in giving to the mother the signal for starting the administration of diazepam. After this preliminary study our policy is now (1) immediate administration of diazepam in clearly stated doses (0.6–0.8 mg/kg per 24 hours in 3 doses) at the first sign of impending illness, continuing for 2–3 days after complete recovery (this regimen is maintained until age 5 years); (2) instruction of all who are concerned with the child, and ensuring the constant availability of the drug. Is this too heavy a commitment for the parents? We do not think so. We are now finding that parents are increasingly willing to comply, provided that the doctors spend sufficient time explaining the aim and benefits of this policy and reassuring them about the safety of the drug, as even unnecessary administration of it for a few days is better than a new FC. Further and more controlled studies are needed. The continuous and adequate treatment of epilepsy precipitated by fever is, of course, mandatory.

Orojejunal feeding in low birthweight infants

Sir,

In transpyloric feeding of neonates the use of a silastic catheter by the technique first described by Rhea *et al.* (1973), and recently improved by Della Pietra *et al.* (1978), avoids the risks due to stiffness of the tube but it has the disadvantage that it often takes a long time to pass the catheter into position. We describe a modification to this technique which allows the tube to be positioned in the jejunum more quickly. We insert the catheter through the mouth, but the nasal route may be used equally well.

Materials. (1) A silicone rubber tube 0.63 mm inner diameter, 1.19 mm outer diameter (Silastic Dow Corning), is cut at 55 cm and its end inserted in to (2) a stainless steel plug 7 mm in length, 3 mm outer diameter, with a central canal 0.8 mm in diameter. (3) A small silastic collar is inserted around the neck of the plug to prevent the silastic tube being disconnected from the plug. (4) A PVC tube (K31 Pharmaseal) and (5) a 0.5 mm rigid nylon thread are cut to lengths of 28 cm. Their diameters are such that the silastic tube can be inserted loosely into the PVC tube and also entered easily by the nylon thread. Tubes (1) and (4) are lubricated with vaseline.

Procedure. The silicone tube (with its nylon thread) and the PVC tube are passed through the mouth and oesophagus into the stomach. With the patient now in a horizontal position and on his right side, the tube is pushed some centimeters deeper and passes easily into the duodenum, as shown by the greenish colour and alkaline pH of the aspirated juice. Once the plug is placed in the duodenum, the PVC external tube is withdrawn gently 2–3 cm at a time while the silicone tube is left in place or lightly advanced. This manoeuvre is helped by the stiffness of the silicone tube with the rigid thread inside. Withdrawal of the PVC tube is continued until its distal end reaches the lower portion of the oesophagus. To avoid pushing the silastic tube too far into the jejunum, it should not be inserted more than two-thirds of the glabella-heel distance. After fixing the PVC tube to the side of the mouth the nylon thread is withdrawn and the silastic tube connected to the infusion apparatus. Radiological localisation of the plug is seldom needed.

We have used this technique to feed 48 premature infants with birthweights between 700 and 1500 g (mean 1083) and gestational ages between 25 and 34 weeks (mean 28), in conjunction with nasal CPAP. In each case the duodenum was easily entered, the procedure requiring 10 to 20 min. No perforation or intussusception occurred (Boros and Reynolds, 1974; Chen and Wong, 1974).

Supported by contract n. 78.00563.83 of the National Research Council (CNR).

Book reviews

Development Defects and Syndromes. By M. A. Salmon and R. H. Lindenbaum. (Pp. 432; illustrated + tables. £30.00 hardback.) HM + M Publishers: Aylesbury. 1978.

The paediatrician or clinical geneticist in search of a syndrome to fit his patient has recourse to a substantial and still growing library of 'syndrome books', for which he is eternally thankful. These have originated almost exclusively from the USA and include Smith's *Recognizable Patterns of Human Malformation*, Bergsma's *Birth Defects Atlas and Compendium*, McKusick's *Mendelian Inheritance in Man* among others. A British addition to this library must therefore be welcomed but, at the same time, it must be judged by the standards set by the earlier American texts. Dr Salmon has assembled information on more than 200 congenital defects and syndromes, with high quality illustrations of most of them. In the first 13 chapters the syndromes are grouped according to the system mainly affected. The last two chapters, on chromosomal syndromes, and an appendix on dermatoglyphics, occupy one-quarter of the book and are Dr Lindenbaum's contribution. There are additional appendices on pedigree symbols and some physical measurements of children.

For each syndrome is given a brief historical bibliography, detailed clinical features and, in most instances, a note on genetic or other aetiological factors. There are some notes about treatment, but this book is designed to help with diagnosis, not with clinical management. Even for genetic counselling, apart from the sections on chromosomal syndromes, the information given is often oversimplified and, occasionally, frankly misleading.

In practical use, the layout of the book is less than ideal. The order of syndromes within sections appears haphazard. The index is a challenge. The reader soon finds that the syndromes are indexed under S rather than under their initial letters, but multiple page references (there are 44 to cleft-palate) are unhelpful. Multiple small errors of omission and commission, in both matter and presentation, spoil what is potentially a very useful book.

I am sorry to have to write critically of a book which is for the most part good, and which represents an enormous investment of labour, However, the truth is that this first edition is not in the same class as its competitors, and at £30 it needs to be. The expenditure of a little more time and a lot more care should make the 2nd edition a winner.

R. W. SMITHELLS

Malignant Diseases of Infancy, Childhood, and Adolescence. Major Problems in Paediatrics, Volume 18. By A. J. Altman and A. D. Schwartz. (Pp. 531; illustrated + tables. £20.00 hardback.) Holt-Saunders: Eastbourne. 1978.

This book is one of a series on Major Problems in Clinical Paediatrics, which aims at providing the general paediatrician with an introduction to the problem of cancer in children, its epidemiology, diagnosis, and management. The book gives good review of the principles of chemotherapy, radiotherapy, the immunology of malignant disease, and the attempts at immunotherapy. Each chapter in the second part of the book deals with a major malignancy. The psychological effects of these diseases and their treatment on the child and the family are discussed. Some of the advice given, while appropriate for the American family and child with malignancy, will need to be modified for this country.

The book is very readable with a clear concise style, up-to-date information—even 1977 references are quoted—and good illustrations. There are some outstanding chapters; one deals with the metabolic haematological, neurological, and infectious complications of malignancy. The section on infections is first class and valuable. It is particularly good because it deals with problems that are likely to be seen in children when they first present or which may complicate their illness after they have left hospital. The subject is rarely considered in other oncology textbooks and was one of the features that convinced me that this was not just another book on tumours, but one that would be of help, not only to
general paediatrician, but to t
specialising in the management of t
conditions.

JOURNAL OF CLINICAL PATHOLOGY

B.M.A. House, Tavistock Square, London WC1H 9JR

o discussion of the vitally important iations from the classical picture and refore of the difficulties in diagnosis; clinical picture of appendicitis in ncy is not mentioned.

he book lacks balance: in numerous tions the common and important ditions in differential diagnosis are er not mentioned, or are mentioned y at the end of the section: faeces ows hydrops of the gall bladder or chal cyst as a cause of abdominal sses. There are sections on traumatic mobilia, acute prostatitis, and the ifying epithelioma of Malherbe, cribed as a 'fairly common disease'. re is a list of 64 causes of hypoglymia, including nesidioblastosis, but the oglycaemic troubles of the diabetic are mentioned. It is remarkable that reas at least 90% of childhood ptoms may be the side effects of drugs se are scarcely ever mentioned in erential diagnosis.

cannot recommend this book.

CYNTHIA M. ILLINGWORTH

Shorter notices

Increased Intracranial Pressure in Children. Diagnosis and Treatment. Major Problems in Clinical Paediatrics, Volume 8. By W. E. Bell and W. F. McCormick. (Pp. 485; illustrated + tables. £21.00 hardback.) Holt-Saunders: Eastbourne. 1978.

Elegantly produced, like all the volumes in this series, and well illustrated. Straightforward accounts of hydrocephalus, tumours, etc. Disappointingly vague on some difficult areas like the diagnosis of cerebral oedema, and whether to do a lumbar puncture in the child with suspected increased pressure.

Pediatric Neurology and Neurosurgery. Edited by R. A. Thompson and J. R. Green. (Pp. 420; illustrated + tables. £17.50 hardback.) SP Medical and Scientific: London. 1978.

Not a textbook, but a collection of reviews of some problems in this field including prenatal diagnosis, migrainous syndrome, some aspects of convulsions including surgery for epilepsy, and rather selective brief chapters on neurosurgery of trauma and tumours. Nothing very new, and no clear indication of the intended audience.

Practical Paediatric Endocrinology. By C. G. D. Brook. (Pp. 142; illustrated + tables. £6.30.) Academic Press: London. 1978.

Although it may be difficult to see who is going to find this 'slim volume' of 129 pages just what they need, those who do read it will discover that the author's potted experience does often provide in a few simple sentences what a larger textbook takes a few pages and much circumlocution to say. At a time when medical texts tend to be painfully overblown, telling the reader more than he wants to know and at far greater length, it is something of a pleasure to find one which tells him, if anything, rather less that he would like.

Archives of Disease in Childhood, 1979, **54**, 248

Referees 1978

We continue to depend heavily on the essential help we get from our referees who assess and, in many cases, suggest significant improvements to the papers. This is the only opportunity the Editors have to acknowledge the work done by them during the past year.

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42**, 109; 1973, **48**, 751).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged.
(11) References in the text. Papers with one or two authors: name author(s) on each occasion the paper is cited with year of publication in parentheses. Papers with more than two authors: use—*et al.* in each citation.
(12) References to be listed alphabetically with full title of article or book; title of journal to be given in full, first *and* last page numbers of journal articles to be given.
(13) Summary to be typed on a separate sheet; and it should say what was done, and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate is £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

SENSORY-MOTOR DYSFUNCTION AND THERAPY IN INFANCY AND EARLY CHILDHOOD *by* **Delmont Morrison** *and* **Patricia C. Pothier,** *both of Univ. of California, San Francisco, California; and* **Katy Horr,** *Miller West Development Center, San Pablo, California.* The theory of and research into sensory-motor therapy with infants and young children, assessment and therapeutic techniques used with these children, and the relationship between sensory-motor and emotional development are discussed. Specific topics include intervention, motor development and dysfunction, habilitation and remediation, and interventions for early occurring emotional disturbances. *'78, 288 pp., 67 il., 2 tables, $14.75*

EATING HANDICAPS: Illustrated Techniques for Feeding Disorders *by* **Demos Gallender,** *Fort Wayne, Indiana. Foreword by* **Virginia Landin.** Designed to remedy the dearth of available literature on the subject, this volume provides guidelines for and demonstrations of eating handicap treatment techniques. The first section of the text covers anatomical and physiological aspects of eating handicaps, while the second presents therapeutic techniques and instructional materials for specific problems. Photographs, diagrams and illustrations augment the text. *'79, 320 pp., 226 il., 5 tables, $19.75*

NEWBORN INTENSIVE CARE: Chemical Aspects *by* **Toshiko Hirata** *and* **June P. Brady,** *both of Univ. of California, San Francisco, California. Forewords by* **Moses Grossman** *and* **I. Newton Kugelmass.** This book explores the physiologic and chemical disturbances that arise during the first month of life, including guidelines for the pediatrician to follow in prescribing treatment. The effects of drugs are discussed as a type of therapy and as a warning to avoid iatrogenic problems. Other topics emphasized in this monograph include cardiopulmonary dysfunctions, temperature control, water and electrolyte regulation, and the use of human milk in the intensive care nursery. The roles of calcium, phosphorus, magnesium and trace minerals are also examined. *'77, 196 pp., 25 il., 14 tables, $19.50*

RADIOGRAPHY OF INFANTS AND CHILDREN: A Problem Oriented Manual of Radiographic and Fluoroscopic Procedures (3rd Ed.) *edited by* **Donald B. Darling,** *Tufts Univ. School of Medicine, Boston, Massachusetts. Foreword by* **John Caffey.** *(16 Contributors)* Completely new material on conventional and computerized tomography, cardiac catheterization, and portable radiography is included in this new edition. A most important feature continues to be a detailed description of procedures and techniques for each anatomical area of examination. *'79, 512 pp. (9 x 12), 1055 il., 48 tables, $60.00*

MEDICAL ASPECTS OF MENTAL RETARDATION (2nd Ed.) *edited by* **Charles H. Carter,** *Sunland Center, Orlando, Florida. (33 Contributors)* The completely revamped Second Edition of this volume offers a singularly useful overview of medical considerations in mental deficiency. The contributors examine and explain genetics and cytogenetics, infections, trauma, cranial abnormalities, poisons, nutrition, and prenatal and postnatal damage. Community diagnostic and treatment centers, cerebral metabolism, treatment with drugs, electroencephalography, neurocutaneous symptoms, degenerative brain conditions, metabolic disorders, and many other related topics are also explored. *'78, 912 pp. (6 3/4 x 9 3/4), 436 il., 47 tables, $65.50*

PEDIATRIC NUTRITION IN DEVELOPMENTAL DISORDERS *edited by* **Sushma Palmer,** *Georgetown Univ., Washington, D. C., and* **Shirley Ekvall,** *Children's Hospital Medical Center, Cincinnati, Ohio. Foreword by* **Phyllis Magreb** *and* **Philip Calcagno.** *(32 Contributors)* Nutritionists from thirteen centers for handicapped children join together to comprehensively analyze the nutritional dimension of developmental disorders. The text spans the spectrum of such conditions, from minimal brain dysfunction to more severe disorders such as cerebral palsy and myelomeningocele. It also covers hereditary metabolic disorders, nutrient deficiency disorders, nutritional assessment, and nutrition for geriatric and normal pediatric populations. *'78, 640 pp. (6 3/4 x 9 3/4), 80 il., 155 tables, $45.75*

Review article

Recognition and management of children with increased lead absorption

J. JULIAN CHISOLM, JR AND DONALD BARLTROP

Baltimore City Hospital, USA, and Westminster Medical School, London

Childhood lead poisoning has been increasingly recognised in the USA where large-scale screening programmes detect some 40 000 cases of undue lead absorption a year. This contrasts with data from the UK where about 100 cases are recognised each year. The situation in other countries is largely unknown, although small surveys have revealed cases from a wide variety of sources. These apparent discrepancies probably reflect differences in clinical awareness, the availability of practical screening tests, and differences in the definition of acceptable degrees of exposure.

Within the last few years practical and effective screening tests for the early detection of undue lead absorption have been developed, but these have not been generally introduced. They include the determination of lead and erythrocyte protoporphyrin (FEP) in microlitre samples of blood. These tests have provided evidence of undue lead absorption from previously unrecognised sources. Thus, dusts contaminated with lead derived from atmospheric deposition, industrial clothing, and degradation of paint films, have now been shown to be important contributory factors. Many children thus affected are asymptomatic, and classical childhood plumbism and encephalopathy at present are rare.

The identification of asymptomatic children has as its objective the institution of effective management in order to prevent serious poisoning and its consequences, and to diminish the potential risks of prolonged low level overexposure. While these risks have not been conclusively demonstrated, it has nevertheless been suggested that subtle neural and behavioural impairments may occur. Moreover, the existence of some children in the population with FEP values that are abnormally high due to lead is no longer considered acceptable.

Sources

Lead is an ubiquitous element with numerous industrial and domestic applications. Children are invariably exposed to lead in general environmental sources—such as food, water, air, dust, and soil—but they may also be exposed to specific and unusual sources including lead paint, lead fishing, curtain, and other weights ingested and retained in the stomach, or the fumes and dust generated by burning lead battery casings, or wood painted with lead pigment paint. Clinical lead poisoning usually occurs as a result of exposure to the second category of items.

General environmental sources. Each major component of the environment—food, water, air, dust, and soil—contributes to the child's total daily intake of lead. Although exposure to lead from these sources is negligible under ordinary circumstances, reports of excess environmental contamination from them are becoming more common. Table 1 lists lead contents for these sources, both under ordinary circumstances and under circumstances of excess environmental contamination.

Food is the principal source of lead for most children. Ordinary daily diets of infants and children may vary widely in lead content; however, limited data suggest that normal diets are associated with average blood lead (PbB) values of 20 μg/100 ml (0·97 μmol/l) whole blood or less (National Academy of Sciences/National Research Council, 1976). More important is the question of contamination of food and drink with exogenous lead. Contamination may occur at the point of origin, during processing, or during preparation and serving at home. Sources of contamination at the point of origin include lead

DONALD BARLTROP, reader in child health

Table 1 *Sources of lead in a child's environment*

- Food
  - Mixed diet (range of means 53–132 μg/day).[1,2] Mean 9·43 μg/kg per day[3]
  - Bottled baby foods (mean 35 μg/l)[4]
  - Human milk 6–59 μg/l[5]
  - *Contaminated sources*
    - Tinned baby foods mean 202 μg/l[4]
    - Cola drink in glazed pottery mug 2000 μg/l[6]
    - Bone meal (health food) 60–190 μg/g[7]
- Water
  - Standards: WHO <100 μg/l[8]
    PHS (USA) <50 μg/l[8]
  - *Contaminated sources*
    - Up to 1850 μg/l[9]
    - 2595 samples[8] 1·4%>50 μg/l, maximum 640 μg/l
- Air
  - Usual lead content 1–2 μg/m³
  - *Contaminated sources*
    - Smelter A[10] ≳ 1·6 km, 8–10 μg/m³
    - Smelter B[11] ≳ 4·0 km, 14–16 μg/m³
- Soil
  - Remote areas 2–200 μg/g[12]
  - *Contaminated sources*
    - Within 1·6 km of smelter B[11] geometric mean ≃ 7600 μg/g
    - Urban residential[13] 9–7890 (median 585) μg/g
    - Garden soil (old mining area)[14] geometric mean 1028 μg/g
    - City parks 194–3357 μg/g[12]
- House dust
  - New inner city homes 2–24 μg/ft² floor surface[15]
  - *Contaminated sources*
    - Old inner city homes 33–486 μg/ft² floor surface[15]
    - Mean 11 000 μg/g[16], suburban 300 μg/g[17], urban 750 μg/g[17]
    - Homes of lead smelter workers: geometric mean 2687 μg/g[18]
    - Homes near smelter A[10] < 1·6 km geometric mean = 22 191 μg/g
      1·7–3·2 km geometric mean 2124 μg/g

[1] Barltrop and Strehlow, 1978; [2] Barltrop and Killala, 1967; [3] Ziegler *et al.*, 1978; [4] Mitchell and Aldous, 1974; [5] Dillon *et al.*, 1974; [6] Harris and Elsea, 1967; [7] Crosby, 1977; [8] National Academy of Sciences/National Research Council, 1977; [9] Beattie *et al.*, 1972; [10] Landrigan *et al.*, 1975; [11] Yankel *et al.*, 1977; [12] National Academy of Sciences Committee on Biologic Effects of Atmospheric Pollutants, 1972; [13] Galke *et al.*, 1975; [14] Barltrop *et al.*, 1975; [15] Vostal *et al.*, 1974; [16] Lepow *et al.*, 1974; [17] Creason *et al.*, 1975; [18] Baker *et al.*, 1977.

arsenate insecticides used on fruit trees, fertiliser made from sewage sludge, and exhaust fumes from cars and lorries from roads adjacent to gardens in which leafy green vegetables such as lettuces are grown. Even so, contamination by the use of lead solder to seal tins is more important. Mitchell and Aldous (1974) found upon examination of 256 tins that the contents of 62% contained Pb>100 μg/l, 37% contained >200 μg/l, and 12% contained >400 μg/l. In similar foods in glass or aluminium containers, only 1% had lead levels >200 μg/l. Much more serious is the cooking and serving of food in ancient pewter or imperfectly glazed ceramic utensils. Milligram quantities of lead can be leached from such vessels, especially by acidic items (e.g. fruits, fruit juices, tomatoes, cider, wine, cola drinks, and soda). Fatal and nonfatal cases of encephalopathy in young children have been traced to the consumption of beverages from improperly lead-glazed vessels (Klein *et al.*, 1970; Sitarz, 1975). Severe lead poisoning in 2 infants was traced to electric kettles with lead-soldered heating coils used to boil water for the infants' formulae (Ng and Martin, 1977; Wigle and Charlebois, 1978). Human milk is reported to contain Pb 6–59 μg/l (Dillon *et al.*, 1974). As lead is secreted in human milk, a nursing mother with increased lead absorption would be expected to produce milk with increased lead content. Lead poisoning has also been reported in people using bone meal as a dietary supplement (Crosby, 1977) and Chinese herbal medicines (Lightfoote *et al.*, 1977).

Drinking water ordinarily contains only traces of lead; however, it may be contaminated if plumbosolvent soft waters of low pH are conveyed in lead pipes (National Academy of Sciences/National Research Council, 1977). Water collected at the tap serviced by 969 public water systems in the USA had an average lead content of 13·1 μg/l and only 1·4% of 2595 samples contained more lead than the drinking water standard set by the US Public Health Service 1962 of 50 μg/l (McCabe *et al.*, 1970). In the UK where soft water is more common, drinking water from approximately 1·7 million household exceeds the WHO limit of Pb 100 μg/l on the first flush sample. Values as high as 1800 μg/l have been reported (Beattie *et al.*, 1972). Similar, but not as severe, contamination of drinking water has been reported in the north eastern USA (National Academy of Sciences/National Research Council, 1977).

The contribution of atmospheric lead to daily intake has been the subject of controversy. Urban air generally contains 1 to 2 μg respirable lead/m³ derived from numerous sources, including exhaust fumes from cars, industrial emissions, and the burning of fossil fuels (World Health Organisation, 1977). Pronounced local variations may occur in relation to stationary sources such as lead smelters (Table 1). Wide variations may also occur seasonally or because of thermal inversions. In London, for example, atmospheric lead concentrations near a road increased during the winter when thermal inversions are most common (D. Barltrop and C. D. Strehlow, unpublished data). For adults, it has been calculated that PbB will increase by 2 μg/100ml (0·097 μmol/l) for each 1 μg/m³ in air (Chamberlain *et al.*, 1978), but it is not yet known whether these values are directly applicable to children. Williams *et al.* (1933) traced an outbreak of severe lead poisoning to the burning of discarded battery casings in the home. More recently, symptomatic lead poisoning was reported in people burning, sanding, and scraping old lead while renovating old homes (Wolf, 1973; Feldman, 1978). Burning of newspaper 'logs' in domestic fireplaces was associated with increased lead absorption in an infant (Perkins and Oski, 1976).

Household dust and soils can be contaminated by the powdering and flaking of old lead paint (Vostal *et al.*, 1974), fallout from atmospheric pollution (Yankel *et al.*, 1977), or by lead-bearing dust being carried into the home on the clothing of workers employed in the lead trades (Baker *et al.*, 1977). The relative contribution to the total lead content of household dust from each of these sources is exceedingly difficult to determine (Bridbord, 1977). In one study in an urban area, Galke *et al.* (1975) found that PbB in children was related to soil lead which, in turn, was related to both automotive traffic density and leaded house paint. Table 2 shows the relationship between dust lead and blood lead level in 38 children aged between one and 6 years. This and other studies indicate that there is a significant correlation between household dust containing <1000–1500 ppm lead and PbB >40 μg (>1·93 μmol) in children. Domestic garden soils may also contain significant amounts of lead. Higher concentrations are generally found within a few metres of the house as a result of decomposition of external painted surfaces (ter Haar and Aronow, 1974; Galke *et al.*, 1975). An increase in the geometric mean blood lead concentration of young children of approximately 8 μg/100 ml (0·4 μmol/l) was found in a district in which the mean soil lead concentration exceeded 10 000 ppm compared with a control district in which the soil lead content was <1000 ppm (Barltrop *et al.*, 1975).

Specific and unusual high dose sources. The ingestion of lead-based household paint is without doubt the main source of serious paediatric lead poisoning (National Academy of Sciences Committee on Biologic Effects of Atmospheric Pollutants, 1972; National Academy of Sciences/National Research Council, 1976). Such paints may contain 1–70% lead, so that tiny flakes contain a highly toxic dose (Fig. 1). Lead poisoning is most prevalent in old poorly-maintained houses in which there is flaking paint, and in families in which young children lack proper supervision. Sporadic cases also occur due to the ingestion of lead fishing weights, lead curtain weights, or lead shot (Seto and Freeman, 1964). Less common sources include jewellery painted with lead to simulate pearl, inhalation of fumes of leaded gasoline (Boeckx *et al.*, 1977), cosmetics (Warley *et al.*, 1968), decals* on cocktail glasses (Natelson and Fred, 1976), and hobbies that use ceramics or leaded stained glass. Although tetraethyl lead poisoning caused by sniffing gasoline is more common in teenagers, cases have also been reported in children under 12.

Table 2 *Comparison of lead in household dust with blood lead in children of lead workers**

No. of children	*Children's blood lead* (μg/100 *ml* ± *SD*)	*Dust lead concentration* (*ppm*)
18	21·8 ± 7·8	0–1000
5	41·6† ± 11·1	1000–2000
5	46·2† ± 21·1	2000–3000
4	65·0† ± 10·4	5000–6000
6	73·3† ± 34·0	7000–80 000

*Employed in secondary lead smelter.

†Significantly > mean level than in children exposed to 0–1000 ppm level of lead in dust (P<0·001).

Conversion: traditional units to SI—blood lead: 1 μg/100 ml ≈ 0·048 μmol/l.

Metabolism and effects

Metabolism. Among people with no unusual lead exposure, the total body lead burden may increase from 0·2 mg at birth to >200 mg during life; however, the increase is limited almost entirely to increasing storage of lead in bone. The concentration of lead in soft tissues normally remains low and relatively constant throughout life (Barry, 1975). Lead incorporated into bone is virtually inert, metabolically speaking. The toxic effects of lead are related to increases in its concentration in the soft tissues. Although there are no data on dose-response for ingested lead in children, it is of interest to compare studies by Kehoe (1961) on chronic adult volunteer lead feeding with the information in children (Mahaffey, 1977). Kehoe found that raised levels of PbB to 80 μg (3·9 μmol) and a likelihood of symptomatic poisoning could be induced after 3 or

*A transfer (picture or design).

4 months with a daily dose of 4 mg Pb. From data on faecal lead, Barltrop and Killala (1967) and Chisolm and Harrison (1956) calculated that the comparable dose in young children is about 1 mg/day—i.e. 25% of the adult dose. These intakes are equivalent on the basis of surface area, and both are about 10 times the normal dietary intake for adults and children. Because lead is slowly metabolised, soft tissue lead concentrations, including PbB, decrease very slowly for months or years after the excessive intake has stopped.

Recent kinetic studies with a stable lead isotope (^{204}Pb) in 5 healthy men suggest a 3-compartmental model for lead metabolism (Rabinowitz *et al.*, 1976). The 2 smaller compartments, one of which is related to excretion of lead via urine and the other to excretion via other routes, consist of blood, soft tissues, and probably, a small exchangeable fraction of lead in bone. The mean lives of lead in these compartments are 35 and 40 days. Rabinowitz *et al.* (1976) estimate that the mean life of lead in bone is about 27 years. Comparable long-term data on steady-state kinetics are not available for young children. Multiple 3-day balances in American infants of under 2 years show wide variation in lead intakes from normal infant foods (0·83 to 22·61 µg/kg per day; mean, 9·43 µg/kg per day) (Ziegler *et al.*, 1978). While net retention for all studies averaged 11% of intake, retention increased to 32% when dietary intake exceeded Pb 5 µg/kg per day. Retention of lead also showed a weak inverse correlation with dietary calcium. The retention of lead by children varies and many children in the short term may be in negative lead balance (Barltrop and Strehlow, 1978). A high incidence of suboptimal dietary intake of calcium was reported in children with increased lead absorption (Mahaffey, 1977; Sorrell *et al.*, 1977). A significant decrease in serum 25-hydroxy vitamin D was reported in children with increased lead absorption (Sorrell *et al.*, 1977; Strehlow and Barltrop, 1978). These clinical studies are consistent with studies in animals which indicate that deficient intake of calcium enhances absorption, retention, and toxicity of lead (Barltrop and Khoo, 1975; Barton *et al.*, 1978; Goyer, 1978). Other experimental studies show that deficient dietary intakes of iron, copper, zinc, and selenium, as well as excessive dietary intake of fat, also increase absorption, retention, and toxicity of lead (Chisolm, 1978). Of interest is the observation that dietary iron in excess of requirements in rats may decrease rentention of lead (Mahaffey *et al.*, 1978).

Effects. In man, the principal target organs for lead are the erythroid cells of the bone marrow, the central and peripheral nervous systems, and the kidney. The inhibitory effects of lead on erythropoiesis are reversible; however, severe acute or chronic clinical lead poisoning may be followed by irreversible injury to the nervous system and kidney. Scattered case reports suggest that acute clinical lead poisoning with PbB >100 µg (>4·8 µmol) may also be associated with impaired uptake of iodine by the thyroid, impairment of the renin-aldosterone system, and ECG changes compatible with myocarditis: the effects are apparently reversible (National Academy of Sciences Committee on Biologic Effects of Atmospheric Pollutants, 1972). The varied cellular effects, which are demonstrable experimentally *in vitro*, are beyond the scope of this report, but are reviewed elsewhere (Vallee and Ulmer, 1972; Granick *et al.*, 1978). The classical concepts of toxicology have been adapted to evaluate lead exposure, absorption, and effect in human populations (Nordberg, 1976) and are summarised elsewhere (Chisolm *et al.*, 1975). In experimental toxicology, the concentration of lead and its effects may be measured directly in affected cells and cell components. In human studies, PbB and chelatable lead* are used as indicators of its concentration in the tissues (internal dose), while various metabolites in blood and urine serve as indicators of its effect in the tissues.

Increase in δ-aminolaevulinic acid in urine (ALAU) is one of the biochemical indicators of lead's inhibitory effects on heme synthesis. The curvilinear dose-effect relationship between PbB and ALAU is such that ALAU increases very sharply as PbB rises above 40–50 µg (1·9–2·4 µmol). The rate of increase is so sharp that ALAU may vary from normal to 5 times greater than normal within the rather narrow 50–60 µg (2·4–2·9 µmol) range in PbB (Fig. 2). Similarly, clinical response also varies, as the full clinical spectrum from no symptoms to fatal acute encephalopathy in children may be found within the PbB range of 100–200 µg (4·8–9·7 µmol) (Table 3). Clearly, responses cannot be ascertained from PbB alone.

New definitions of the terms 'critical organ' and 'critical effect' relative to lead have been proposed (Nordberg, 1976) and have important implications for preventive medicine. Derangement of Hb synthesis in the erythroid cells of the bone marrow is now considered the critical or first adverse effect. Current preventive health policies rest on the assumption that intervention on the basis of biochemical evidence of derangement of Hb synthesis will suffice to prevent the more serious and possibly long-term adverse effect of lead in the nervous system and kidney. It should be borne in mind,

---

*Chelatable lead = quantity of lead excreted in urine after standardised dose of CaEDTA or D-penicillamine.

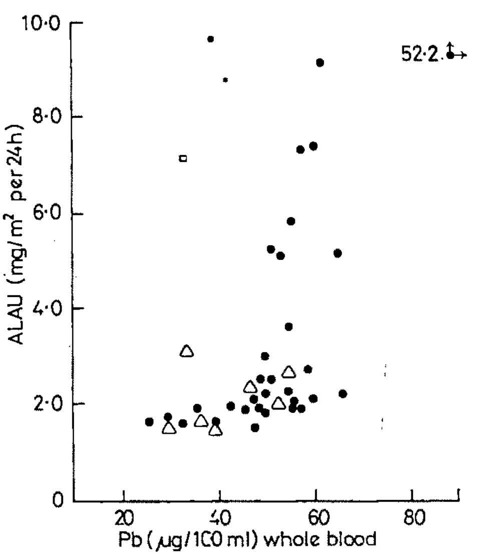

Fig. 2 *Relationship between PbB and ALAU in children. For children with PbB between 8 and 30 µg, normal daily excretion averages 1·1 ± 0·4 mg ALAU/m² per 24 h (upper limit of normal 2·3 mg ALAU/m² per 24 h) (Chisolm et al., 1976). Daily output of ALAU, which is related to surface area in children, increases sharply as PbB increases above 50 µg; however, there are pronounced differences in ALAU among individuals with PbB in the 50–60 µg range. The two anomalous cases shown as □ and △ had sickle cell disease and sickle cell trait, respectively.*

Table 3 *Relationship between blood lead concentration and symptoms of plumbism in children**

Clinical group	*n*	*Blood lead concentration* (µg/*100ml*)	
		Median	*Range*
Acute encephalopathy			
Fatalities	98	295	138–750
Survivors	99	270	88–1,310
Acute plumbism (non-encephalopathic)	40	135	63–450
Increased lead absorption (? clinical symptoms)†	46	85	60–300

*Adapted from National Academy of Sciences Committee on Biologic Effects of Atmospheric Pollutants (1972), as compiled from reports of Chisolm and Harrison (1956), Chisolm (1962, 1968), and Baltimore City Health Department.

†Although some children in this group had nonspecific symptoms compatible with plumbism, they also had other conditions which give rise to the same symptoms, making clinical diagnosis uncertain.

For conversion to SI units see footnote to Table 2.

however, that biochemical indicators of lead's effects on heme synthesis in erythrocytes are extraordinarily sensitive and not entirely specific for lead: FEP is raised in both iron deficiency and increased lead absorption, and δ-aminolaevulinic acid dehydratase (ALAD) is a zinc-dependent enzyme inhibited by lead (Chisolm, 1978).

Heme synthesis in bone marrow

All cells synthesise heme for their own hemoproteins (Hb, myoglobin, catalase, cytochromes, P-450, etc.) via a common metabolic pathway. Experimental data show that lead interferes with this process in all organs so far studied; however, the erythroid cells of the bone marrow are the most sensitive (Moore, 1975; Nordberg, 1976). There are 6 major enzymatic steps in the formation of heme. In lead-poisoned adults, increased activity of δ-aminolaevulinic acid synthetase, partial inhibition of ALAD, coproporphyrinogen oxidase, and ferrochelatase has been demonstrated (Wada *et al.*, 1972; Campbell *et al.*, 1977). These enzymatic changes account for the pattern of metabolites found in blood and urine, which is pathognomonic for lead; namely, decreased *in vitro* activity of ALAD in circulating erythrocytes, increased FEP, increased excretion of ALAU and coproporphyrin (CPU), and normal or nearly normal excretion of porphobilinogen and uroporphyrin in urine. Excess lead also impairs the uptake and use of iron, as well as the synthesis of globin in developing erythrocytes. In children the circulating erythrocytes are hypochromic and microcytic, and reticulocytosis is sometimes found. The morphology of the peripheral blood in children with plumbism is virtually identical with that found in iron deficiency, a condition with which plumbism is often associated. Lead also impairs the activity of 5′-pyrimidine nucleotidase, which accounts for the basophilic stippling of erythrocytes associated with severe and chronic plumbism (Valentine *et al.*, 1976). When PbB >60 µg, Hb and haematocrit are significantly reduced (Rosen *et al.*, 1974; Landrigan *et al.*, 1976). Pueschel *et al.* (1972) and Betts *et al.* (1973) have reported an increasing frequency of reduced Hb when PbB>40 µg. These differences are probably attributable to differences in the prevalence of iron deficiency in the populations of children studied. The PbB threshold for increase in ALAU in children is between 40 and 50 µg Pb. Although the threshold for FEP in children is apparently lower, the increase is generally slight—up to about 30 µg Pb—above which it increases exponentially (Stockman *et al.*, 1975; Hanna *et al.*, 1976; World Health Organisation, 1977). FEP may also be increased in iron-deficient children with PbB<30 µg (<1·5 µmol) (Stockman *et al.*, 1975; Koller *et al.*, 1978; Strehlow and Barltrop, 1978).

Kidney and bone

Clinical lead poisoning may be associated with both acute and chronic effects in the kidney. In children with acute encephalopathy and PbB>150 μg (7·2 μmol), the full Fanconi triad (hyperaminoaciduria, glycosuria, and hyperphosphaturia) in the presence of hypophosphataemia has been reported (Chisolm, 1962). The Fanconi triad is reversible. Children with a history of clinical plumbism during the preschool years in the USA have not shown evidence of residual renal injury in adolescence or early adult life (Tepper, 1963; Chisolm, 1970). This experience differs from that in Australia where an increased frequency of late lead nephropathy was reported (Nye, 1929; Henderson and Inglis, 1957). Emmerson (1968) described the syndrome as characterised by progressive loss of renal function, often with hyperuricaemia and saternine gout, terminating with renal failure. Some of these patients were also mentally retarded and had pes cavus deformity due to old peripheral neuropathy. In the Australian children, symptomatic episodes of plumbism extended well beyond the preschool years, up to 10 to 12 years. It seems likely that prolonged poisoning was an important factor in the irreversible renal injury sustained by the Australian children.

The bands of increased density at the metaphyses of growing long bones characteristic of lead poisoning in children are generally limited to those who have sustained PbB>50 to 60 μg (Betts *et al.*, 1973). Although these *x*-ray changes are generally called 'lead lines', a major factor is distortion of bone architecture and increased mineral deposition caused by lead. Their presence suggests that one of the body's important compensatory mechanisms—storage of excess lead in bone—is being impaired.

Neurological and behavioural effects

Acute lead encephalopathy is the most severe clinical form of lead poisoning. Pathologically, it is characterised by extensive cerebral vasculopathy and massive oedema of the brain (Clasen *et al.*, 1974). It is most common during the summer months in children of under 3. Before the advent of chelating agents, 65% of severe cases terminated fatally. In recent years, chelation treatment with a combination of BAL and CaEDTA has reduced mortality to less than 5% (Coffin *et al.*, 1966; Chisolm, 1968). When chelation treatment is begun *after* the symptoms of acute encephalopathy appear, the incidence of severe permanent sequelae—such as mental retardation, seizure disorders, blindness, and hemiparesis—is estimated at 25 to 50%, even if abnormal re-exposure is promptly stopped (Chisolm and Harrison, 1957; Byers, 1959; Chisolm, 1973). Byers and Lord (1943) reported that 19 of 20 children with at least one symptomatic episode of plumbism subsequently did poorly in school, despite the fact that standard psychometric tests indicated normal intelligence. Failure in school was attributed to behavioural disorders, lack of attention, perseveration, and visual-motor impairment. In a similar group of 425 children, Perlstein and Attala (1966) found that 39% sustained severe neurological sequelae. Although data on PbB are not systematically given, the data in Table 3 suggest that they were describing the chronic course and outcome in children in whom PbB repeatedly exceeded 80 to 100 μg. In the USA, screening data currently reported to the Center for Disease Control indicate that 3 to 20% of preschool children have increased lead absorption, as shown by PbB in the 30 to 80 μg range. Most are asymptomatic, while mild nonspecific symptoms compatible with early plumbism are reported in a few. In children living near primary smelters (Landrigan *et al.*, 1975) or in the homes of workers who carry fine particulate lead home on their clothing (Baker *et al.*, 1977), the proportion of children with increased lead absorption is somewhat higher. Even so, most are asymptomatic. Whether such children are at significant risk for subtle, but significant neurobehavioural impairment has aroused much concern. During the postnatal phase of rapid neurodevelopment, which in children extends from birth to 2 or 3 years, the brain may be especially vulnerable to nutritional and toxic insults (Dobbing and Smart, 1974). Evidence is still incomplete and clinical studies have given conflicting results. Experimentally, lead can be shown *in vitro* to inhibit the calcium-mediated release of neuro-transmitters, cause demyelinisation of the axon, impair oxidative metabolism in the brain, and impede transmission at the neuromuscular junction (Granick *et al.*, 1978). Animals dosed with lead during the phase of rapid postnatal neurodevelopment showed slowed learning (Brown, 1975), maturational delay (Grant *et al.*, 1976), and scotopic defects (Bushnell *et al.*, 1977). During infancy, PbB values in the range of 40 to 80 μg were reached in these experiments, although the deficits were not shown until after PbB levels had returned to normal. Thus, the experimental data suggest that increased lead absorption during the phase of rapid neurodevelopment may induce later neurobehavioural deficits. Some animal studies are confounded by inadequate nutritional controls (Barltrop and Khoo, 1975; Reiter *et al.*, 1975). In view of other experimental studies which indicate that deficiencies of iron and zinc may have similar subtle adverse neurobehavioural effects, resolution of this question still awaits appropriately designed studies.

Clinical studies have also given conflicting results. Lansdown *et al.* (1974) and McNeil *et al.* (1975) did not find deficits at school age, and Kotok *et al.* (1977) attributed the deficits they found to pre-existing factors. Conversely, Albert *et al.* (1974), Rummo (1974), and de la Burdé and Choate (1975) did find deficits at school age which they attributed to lead. The only workers who have conducted a study prospectively from birth to 8 years of age are de la Burdé and Choate (1975), and their findings are similar to those of Byers and Lord (1943), inasmuch as poor performance in school was also attributable primarily to behavioural problems. These various studies suggest that no significant impairment has been found in children from higher socioeconomic classes who were well nourished and who generally had PbB<50 μg. Positive findings have been in children from the lowest socioeconomic class in deteriorated urban areas whose source of lead was paint, and who sustained PbB>50–60 μg, and in whom poor nutritional status was strongly suspected. Neurobehavioural impairment at school age has been related to raised levels of lead in shed deciduous teeth (Needleman *et al.*, 1978); however, these data do not give a retrospective estimate of earlier blood and soft tissue lead levels. David *et al.* (1972) were the first to suggest that asymptomatic increased lead absorption might be one of the aetiological factors in hyperactivity in children. This provocative hypothesis has yet to be tested adequately. Initially, experimental studies in which high doses of lead were used in suckling animals seemed to confirm the hypothesis of David *et al.* (1972); however, subsequent studies with lower doses have generally not resulted in increased locomotor activity (e.g. Reiter *et al.*, 1975).

Peripheral neuropathy is rare in children. Among the 15 cases recently reported from America, 7 were in children with sickle cell disease (Anku and Harris, 1974; Erenberg *et al.*, 1974). This striking clinical observation may be important, inasmuch as sickle cell disease is apparently associated with secondary zinc deficiency (Prasad *et al.*, 1975), and studies in animals indicate that zinc is protective against lead.

Management

Clinical management. Paediatric intervention should be started in the presymptomatic phase in order to lessen the risk of serious injury to the nervous system. Indeed, most referrals today are likely to be asymptomatic children who have been identified in screening programmes, epidemiological surveys, or as housemates of an index case of poisoning. The nature of the exposure (see Environmental management), as well as the age of the child and his nutritional, genetic, developmental, psychosocial, and behavioural status should be weighed in making a plan of management tailored to his needs. Children under 3, in whom pica is common (Barltrop, 1966), and in whom the rapid postnatal phase of neurodevelopment is not yet complete, usually need closer follow-up than older children. Adequate dietary intakes, particularly of calcium, iron, and zinc must be assured, while excessive dietary fat is to be avoided. Response to medicinal iron, which is often required, can be monitored by serial FEP tests (Fig. 3).

For those who are intolerant of milk, 'lactose-free' milk products, or an alternative source, will be necessary to ensure an adequate calcium intake. Clinical experience and the occurrence of zinc deficiency suggest that those with a sickling disease (Hb SS, SC, or S-thal) have a higher susceptibility to lead and so should receive priority for transfer to a 'low-lead' environment. Mentally retarded children, in whom chronic pica is prevalent, should receive PbB and FEP tests periodically as part of their regular health care, even if initial tests give normal results.

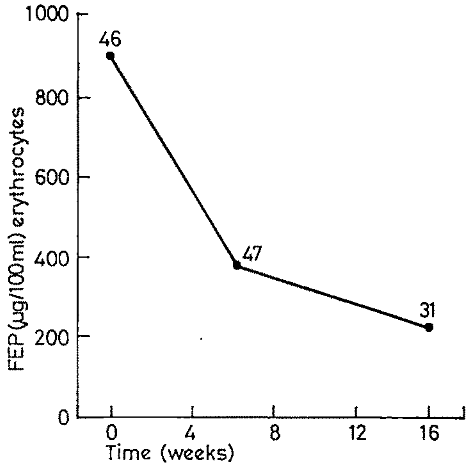

Fig. 3 *Combined influence of iron deficiency and increased lead absorption on erythrocyte protoporphyrin (FEP). Line connecting points shows trend in FEP, while numbers adjacent to points show PbB values. Clinical history and additional data (serum FE = 21 μg/100 ml; (3·76 μmol/l); TIBC = 544 μg (97·14 μmol/l); % saturation = 3·9%) indicated deficient dietary intake of iron and residence in a dilapidated old house. During the first 7 weeks of treatment with iron, FEP decreased from 900 to 400 μg/100 ml erythrocytes, and haematocrit increased substantially, although PbB remained unchanged. The family then moved from an old house to public housing in Baltimore, USA, where the use of lead-containing paints has been prohibited for the last 40 years. Iron treatment was continued and both PbB and FEP decreased further.*

The term pica refers to the magpie, a bird of both capricious and voracious appetite. The habit of pica may be defined as the repetitive search for and ingestion of nonedible items. In children, it starts at about 12 months and occurs in about half of one- to 3-year-old children (Barltrop, 1966). Its aetiology is not understood. Lourie *et al.* (1963) considered pica an important symptom of familial stress and disorganisation, with resultant lack of mothering. Success in ameliorating a child's pica often depends on the degree to which such family problems can be resolved.

In heavily contaminated areas, periodic testing throughout the preschool years is indicated. A child with increased lead absorption should be checked every 3 months for at least a year until PbB and FEP steadily decrease and stabilise at or near the normal range, indicating satisfactory abatement of hazards and probable diminution of pica. Sometimes initial clinical evaluation may suggest the need for follow-up, even if the initial PbB levels are normal, as an infant with pica may subsequently gain access to a hazardous lead source (Fig. 4). Reigart and Whitlock (1976) found that a raised level of FEP, together with normal or minor increase in PbB is often predictive in young children of subsequent increase in PbB to potentially hazardous levels. The renovation of old leaded dwellings is hazardous not only for workmen (Feldman, 1978), but especially for young children who can experience a sharp rise in lead absorption (Fig. 5), even to symptomatic levels. Young children and pregnant women should seek residence elsewhere—night and day—until renovation is complete and the debris removed from the premises, an admonition not always heeded. The data in Fig. 5 illustrate another common occurrence; incomplete abatement of residential lead hazards with a spike in PbB in the child on return home.

While removal of lead from the child's environment is the key to successful clinical management, selective use of chelating agents can be a valuable adjunct. Three agents are used: edathamil calcium disodium (CaEDTA), 2, 3-dimercapto-1-propanol (BAL), and D-penicillamine (PCA). According to principles described elsewhere (Chisolm, 1968), the greater the physician's estimate of soft tissue lead

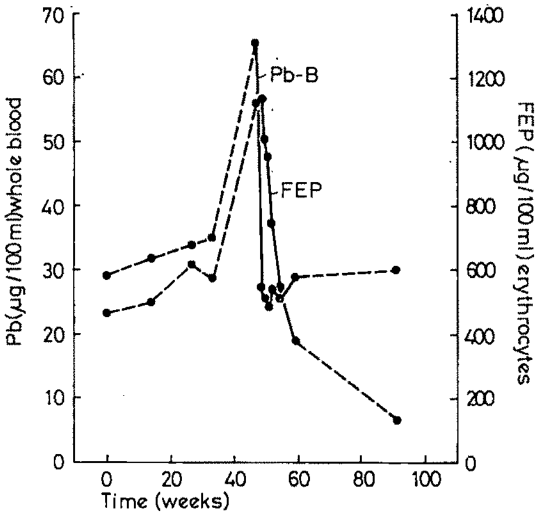

Fig. 4 *PbB and FEP in an iron-deficient infant with indiscriminant pica.*
Initial data showed residence in safe housing, normal lead absorption, and iron deficiency in a 12-month-old infant; however, a positive history of pica, visits to relatives in poor housing, and a working mother indicated the need for prolonged follow-up. Sharp rise in PbB and FEP coincided with relegation of the infant's care to young irresponsible relatives during the summer. Patient was treated (solid portion of line) in hospital with chelating agents, dietary correction, medicinal iron, behavioural management to lessen pica, and return to safe housing area.

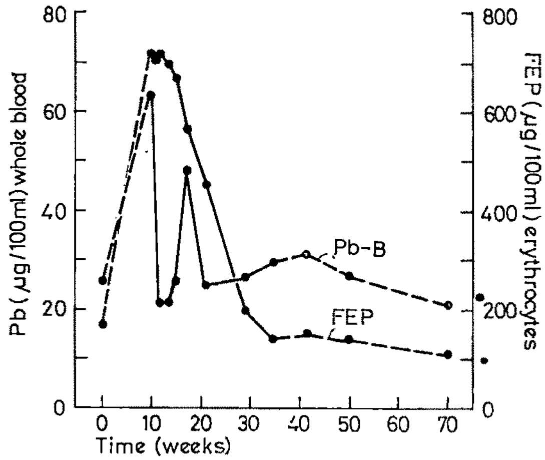

Fig 5 *PbB and FEP changes in an infant during deleading of an old home.*
The infant remained in the home during burning, scraping, and sanding of old lead-bearing paint. Both PbB and FEP levels increased dramatically during a fortnight of intense exposure. The infant was placed in hospital and treated with chelating agents, medicinal iron, and prophylactic amounts of copper and zinc. A rise in PbB from 22 to 47 µg (1·06 to 2·3 µmol) during fortnight immediately after discharge indicated incomplete hazard abatement. Family thereupon moved to modern 'lead-free' public housing. PbB decreased promptly, while FEP continued to decrease.

concentrations, the higher the initial dosage of chelating agents should be. Conversely, because of the curvilinear relationship between PbB and chelatable lead, *arithmetic* decreases in PbB are associated with *exponential* decreases in the amount of lead mobilised and excreted in the urine (Chisolm *et al.*, 1976). It follows that their use in children with slightly increased soft tissue lead concentrations may be of such limited benefit as to be outweighed by the fact that these agents also remove substantial amounts of zinc and other trace metals which are protective against the toxicity of lead. Parenteral CaEDTA and BAL are considered primary drugs, while oral PCA serves well as a secondary sustaining agent if long-term treatment appears warranted and a low lead environment can be found for the child. Under no circumstances should chelating agents be given while excess lead intake continues. Patients on PCA must be closely monitored for renal (nephrotic syndrome) and haematological reactions (especially neutropenia). CaEDTA is a nonmetabolisable drug which is excreted exclusively by glomerular filtration. Fatal reactions have occurred when its use is continued in anuric patients. CaEDTA and PCA should not be used in asymptomatic or mildly symptomatic patients with intercurrent renal disease. BAL is contraindicated in patients with acute hepatocellular injury and in males with G6PD deficiency. These and other precautions are described more fully elsewhere (Chisolm, 1968; United States Public Health Service, 1978). Details of drug dosage and the treatment of acute encephalopathy are given in the Appendix.

The use of chelation treatment in asymptomatic or questionably symptomatic children with increased lead absorption is controversial, particularly the long-term oral use of PCA. The retrospective study of Albert *et al.* (1974) suggests that chelating agents in such cases may reduce the prevalence and severity of the neurobehavioural sequelae of early childhood plumbism. For children with PbB in the 30–50 μg range, correction of nutritional deficits and steps to reduce exposure, including stringent dust control in the home, should suffice. A disproportionate increase in FEP (Fig. 3) is suggestive of concurrent iron deficiency which should be corrected. An overview of current experimental data and studies on humans suggests that the combination of PbB >50–60 μg and FEP >300 μg/100 ml erythrocytes in a child under 2, and >500 μg/100 ml (8·90/μmol/l) erythrocytes in a child over 2, probably constitute reasonable clinical indications for at least brief courses of chelation treatment. The indication is further strengthened if long-bone *x*-rays are positive for 'lead lines'. The unresolved question is whether or not PbB concentrations sustained >50–60 μg over a period of months or years, even in the absence of continued abnormal ingestion, carries a significant risk for CNS injury.

Lead poisoning and increased lead absorption must be treated as chronic disorders. Often, the doctor, environmental hygienist, public health nurse, and medical-social service personnel have to work as a team. In certain areas of the USA, lead poisoning is a reportable disorder. Children surviving encephalopathy may require long-term management for seizure disorders, gross behavioural aberrations, and special school placement. For children who must perforce live in substandard housing, adequate nutrition may improve their resistance to lead. The effectiveness of any tentative long-term management is best judged by the child's biological response. Satisfactory control of emissions from stationary sources will be followed by decreases in PbB in the nearby population (Yankel *et al.*, 1977).

Environmental management. The objectives of environmental management after the discovery of a case of excessive exposure to lead are twofold: (1) the prevention of re-exposure of the child and (2) the protection of other individuals who may be currently or subsequently exposed. This means that the identified source must be removed or at least measures taken to render it unavailable to young children.

Domestic sources

The most common sources in the home are accessible painted surfaces. The ideal solution is the complete removal of all lead-containing paint accessible to children and its replacement by an appropriate low-lead paint (lead-free) intended for interior use. Although legal provisions to enforce such action are available in some parts of the USA, this is not universal. Much depends on the ownership of the home, the attitude of local housing authorities, and the socioeconomic status of the family. Substantial amounts of fine particulate lead may be released during the course of remedial work, and these may be sufficient to cause significant additional burdens for children who remain resident in the home during renovations (Fig. 5). It is important that all pre-existing paintwork be removed, and that the house is not merely redecorated with an additional layer of paint. Other temporary measures may include accessible painted surfaces being covered with an adhesive plastic material (United States Public Health Service, 1978).

Other domestic sources including glazed ceramics, toys, and surma*, (Table 1) should be controllable by simple advice and removal. Similarly, industrial clothing contaminated with lead should never enter the home, although this may be difficult to enforce. The lead hazard of some industrial processes is not always appreciated (Gafafer, 1966). If heavy contamination of clothing occurs, the only solution is to ensure that the worker has the opportunity of bathing and changes his shoes and clothing at the workplace at the end of each shift. In addition, facilities for the laundering of industrial clothing must be available at the place of work, rather than in the home. Domestic sources of lead may result in heavy contamination of household dust on the floor and in the upholstery of furniture. If this has occurred, then as complete removal as possible of dust should be undertaken, using a vacuum-operated device.

---

*Cosmetic used by Asians which sometimes contains lead sulphide.

Contaminated drinking water is usually the consequence of lead plumbing or storage tanks in an area where the water has a high degree of plumbosolvency. The only immediate solution is to provide an alternative supply from a less hazardous source, although the exposure may be mitigated by merely flushing the system for several minutes before use. This is particularly important after prolonged periods in which the water has been static in the delivery system, for example, in the early morning. The only ultimate solution is the removal of lead from the delivery system. While this may be possible for an individual family with a localised source, for example, an improperly soldered joint in a copper pipe or an imperfectly manufactured electric kettle, it may not be immediately applicable if the use of lead in the delivery system is extensive. Thus, in the UK, it has been estimated that the cost of meeting the WHO 'European' standard of 100 μg/l would be of the order of £1000 million. In this context, it should be noted that in the US, a water standard of 25 μg/l has been suggested (National Academy of Sciences/National Research Council, 1977). From a prophylactic standpoint, effective measures may require action at a national rather than a local level. Such measures may include introducing regulations governing the import, manufacture, or sale of lead-based cosmetics, toys, ceramic ware, paint, and graphic materials liable to be used by children at home or in educational establishments. There is little international agreement concerning such regulations. In the USA, the lead content of paints for domestic use has been severely restricted and a regulation restricting this to 0·06% has been promulgated, whereas in the UK a value of 1·0% is still permitted (0·5% for toys and nursery furniture).

Nondomestic sources

Problems arising outside the home are only likely to be found in relation to industrial activities either current or defunct. This may result from direct access to tips or mine tailings of high lead content or dispersion of lead-contaminated dusts from their surface. In addition, lead may be dispersed in the atmosphere as respirable particulate material, the impact of which will depend on local topography and climatic conditions. In such cases, whole communities rather than individuals are likely to be affected and the solutions require the collaboration of several agencies. It is often difficult to identify the routes of transmission of lead in such circumstances or indeed to assess their relative significance. Immediate measures should depend on the severity of the cases. In the event of exposures of sufficient degree to result in frank plumbism, the only ethical choices are either the evacuation of the community or the immediate cessation of emissions. Ideally, atmospheric dispersion from many industrial sources can be substantially diminished by the introduction of effective baghouse (filtration) equipment. Re-entrainment of lead by wind dispersion from unprotected tips and mine tailings can be checked by either removal or covering with an uncontaminated layer of earth. Such sources should be rendered inaccessible to children. The management of contaminated soils and dusts in houses and villages adjacent to industrial sources is not generally amenable to simple measures. Paving with impervious material is expensive and aesthetically unsatisfactory. Treatment of earth surfaces with a resin or similar material in order to diminish wind dispersion may be temporarily effective, but cannot be applied to land used for the cultivation of crops. Frequently, the only solution is the physical removal and replacement of soil in the heavily contaminated inhabited area. However, there are as yet no generally agreed standards for the permissible lead content of surface soils in relation to dwellings or for other uses. Similar considerations apply to the permissible content of respirable lead in the atmosphere. It has been calculated that each 1 μg/m^3 lead contributes approximately 1–2 μg/100 ml to the content of lead in blood. There are as yet no generally agreed air quality standards, although values in the range 1–5 μg/m^3 have been suggested. In the EEC countries a standard of 2 μg/m^3 for residential areas remote from motorways and industry has been recommended, while the US Environmental Protection Agency has advocated 1·5 μg/m^3 of air. It should be noted, however, that such standards are usually intended to apply to mean monthly or even annual values and that transient or seasonal fluctuations may occur.

Conclusions

There is no longer any reasonable doubt that acute lead encephalopathy and recurrent symptomatic plumbism in children can, in a high proportion of cases, result in severe residual CNS injury, including seizure, mental retardation, severely handicapping behavioural disorders and, in rare cases, blindness, and hemiparesis. In asymptomatic or mildly symptomatic plumbism, clinical studies have given conflicting results. There is some evidence, however, that a sustained PbB >50–60 μg/100 ml during early childhood carries a significant risk of subtle neurobehavioural impairment, but not for the more serious sequelae associated with symptomatic lead poisoning. Such subtle deficits do not become evident until later in childhood. Data on immature animals also indicate that subtle cognitive and visual deficits, but not hyperactivity, may result when PbB is sustained in the 50–100 μg range. The effects of unsustained increases of PbB in the same range are unknown. Concurrent marginal or frank nutritional deficiencies especially of iron, calcium, and zinc, as well as the habitual overuse of fat in the diet, may be important cofactors in determining the final clinical outcome. A thorough history to identify all potential sources of overexposure to lead in the child's environment, followed by identification of the actual sources is essential. Separation of the child from sources of lead constitutes the cornerstone of any therapeutic plan. Although the use of combined chelation treatment in acute lead encephalopathy can be life-saving, treatment started *after* the onset of severe symptoms will not prevent the occurrence of CNS sequelae in survivors. Modern screening tests permit the detection of plumbism before the onset of symptoms. The indications for the use of chelating agents in asymptomatic increased lead absorption are uncertain. Emphasis is placed on the need for individual management and long-term follow-up to determine the trends in each child's course. Pica, the response to assimilated lead, and the pattern of neurodevelopment during the first 3–4 years of postnatal life, may make the young child more vulnerable to overexposure to lead than older children and adults.

Appendix: treatment of acute plumbism

In acute lead encephalopathy, treatment with combined BAL-CaEDTA in the following dosage is recommended: BAL, 500 mg/m^2 per 24 h; CaEDTA, 1500 mg/m^2 per 24 h. To lessen pain, procaine is added to the 20% CaEDTA concentrate in a final concentration of 0·5%. Each drug is given by deep IM injection at separate sites simultaneously in divided doses 4-hourly for 5 days. This is maximum dosage. It is unsafe to continue it beyond 5 days. In asymptomatic or very mildly symptomatic patients with confirmed PbB in excess of 80 to 100 μg, the above regimen may be modified as follows: discontinue BAL when used after 48 hours but continue CaEDTA for an additional 48 to 72 hours in reduced dosage of 1000 mg/m^2 per day divided into two or three doses at 8- to 12-hour intervals. If CaEDTA is used alone in patients with initial PbB <80 to 100 μg, 500 mg/m^2 12-hourly either by deep IM injection or by continuous IV infusion for 3 to 5 days should suffice. Patients receiving BAL should be placed on parenteral fluids or clear liquids orally to minimise the vomiting which BAL often causes. Brief courses of chelation treatment are virtually always associated with rebound in PbB, presumably as a result of internal redistribution of lead (Fig. 6). When it is considered desirable to lessen this rebound and maintain soft tissue lead at a low level until the excess lead has been either excreted or well sequestered in bone, an initial course of CaEDTA, with or without BAL, may be followed by oral PCA. Oral PCA should be continued until FEP decreases to near normal. Even so, such patients must still be checked for delayed rebound in PbB and FEP. Although clinical studies are not available, experimental data strongly suggest that prophylactic amounts of iron, zinc, and copper should be given during long-term treatment with PCA to prevent depletion of these metals. Oral dosage of PCA

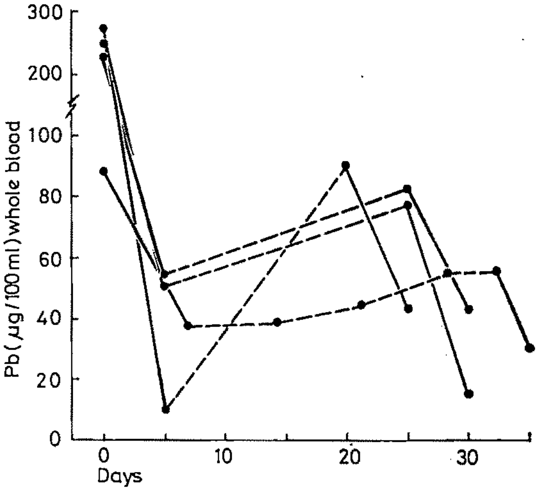

Fig. 6 *Rebound in PbB between brief courses of chelation treatments.*
These data were obtained in 4 children continuously in hospital for 30 to 40 days. The solid bars show the decrease in PbB during 5-day courses of CaEDTA (or BAL-CaEDTA), while the broken lines show the upward trend in PbB between courses of chelating agents. Serial measurements of ALAD, ALAU, and CPU, but not FEP, show virtually identical trends.

should not exceed 600 mg/m^2 per day, given on an empty stomach in chilled fruit juice, if necessary, 2 hours before breakfast.

The use of combined BAL-CaEDTA treatment for acute lead encephalopathy is described in detail elsewhere (Chisolm, 1968). The salient points are: (1) appropriate supportive therapy is just as vital to survival as chelating agents, (2) BAL-CaEDTA therapy must be instituted *promptly*, (3) parenteral fluids are restricted to basal requirements and a minimal estimate of replacement of deficits caused by dehydration, protracted vomiting, or concurrent renal injury due to lead. Adequate, but not excessive urine flow must be established before CaEDTA can be given. Mannitol may be necessary to re-establish adequate urine flow. Initial control of seizures is perhaps best achieved by diazepam, while further convulsive activity should be controlled with paraldehyde until the patient is substantially improved, after which long-term anticonvulsant treatment with phenylhydantoin may be instituted.

Surgical decompression and hypertonic solutions to relieve intracranial pressure and reduce cerebral oedema are contraindicated. Time should not be wasted in attempts to evacuate residual lead from the bowel by enema. Such attempts are futile and the attendant delay jeopardises the child's life. In symptomatic children who do not have obvious evidence of increased intracranial pressure, it is judicious to treat them in hospital as possible incipient cases of encephalopathy and so monitor parenteral fluids and urine output and restrict oral intake during the initial 24 to 48 hours of treatment.

Annotations

Red cell aplasia in children

Red cell aplasia in children is a condition characterised by failure of erythropoiesis, with normal production of white blood cells and platelets. The disorder is either acquired or constitutional (congenital or inherited). The constitutional disorder is usually permanent, while the acquired variety is often transient, and thereby differs from adult pure red cell aplasia. As the treatment and prognosis of a child with anaemia depend on the diagnosis, the distinctive feature of each disorder is described.

Constitutional red cell aplasia: Diamond-Blackfan anaemia

Children with anaemia without pancytopenia were first described in 1936, and again in 1938.[1,2] More than 200 cases have now been reported and were reviewed recently.[3,4] The diagnostic criteria include: (1) normochromic, often macrocytic anaemia without reticulocytopenia, developing early in childhood; (2) bone marrow with normal cellularity and usually a deficiency of red cell precursors (although these are occasionally normal or even increased); (3) normal or slightly decreased leucocyte counts; (4) normal or often increased platelet counts. The original term, 'congenital hypoplastic anaemia' was used because it was thought that the marrow was hypoplastic. The eponym, 'Diamond-Blackfan anaemia' is useful, since it justifiably indicates no specific aetiology of the disorder.

The diagnosis is made most commonly in infancy. 25% of reported infants were anaemic at birth, 65% by 6 months, and 90% by one year. Rare cases were diagnosed between 2 and 6 years of age. The male:female ratio is one. Most reported cases are Caucasian, but Blacks, Orientals, and Indians have been reported.

The inheritance of Diamond-Blackfan anaemia is not clear. Three-quarters of the reported cases were sporadic. Two families had parental consanguinity, and 13 families had more than one affected child. Thus autosomal recessive inheritance was suggested. However, 6 families were reported in which there was anaemia in one parent. In 3 additional families, the fathers had more than one affected child by unrelated wives. In a few families, one child had Diamond-Blackfan anaemia, while a sibling or a parent had transient anaemia (see below).

Mothers of affected children have reported an increased incidence of miscarriages or stillbirths. 10% of such infants were born after problem pregnancies, such as toxaemia, haemorrhage, and a variety of illnesses. Low birthweight occurred in 10%, divided equally between preterm infants and those who were small for gestational age.

Physical anomalies were reported in approximately 30% of cases (Table 1). The most common finding is short stature. Other abnormalities are microcephaly, cleft palate, abnormal eyes, web neck, and deformed thumbs. The anomalies resemble those seen in patients with Fanconi's pancytopenia, but are usually not as prominent in the children with Diamond-Blackfan anaemia. Abnormal thumbs were reported in 20 cases.[5] 10 children had triphalangeal, and 7 had duplicated or bifid thumbs.

All patients are anaemic at the time of diagnosis. The anaemia is normochromic, but it is macrocytic in one-third. Reticulocyte counts are usually zero. White blood counts are normal or slightly decreased,

Table 1 *Physical findings in 229 patients with Diamond–Blackfan anaemia*

Abnormality	*No. of cases*
Height < 3rd centile	36
Microcephaly	9
Macrocephaly	2
Palate	
Cleft	12
High arched	3
Eyes	
Strabismus	6
Hypertelorism	8
Other (epicanthal folds, ptosis, blue sclerae, cataracts, microphthalmia)	14
Neck—short, and/or webbed	14
Thumbs	
Triphalangeal	10
Duplicated	7
Subluxed	2
Malformed	1
Mental retardation	9
Renal—caliectasis, partial horseshoe, double collecting system	7
Hypogonadism	5
Skeletal—scoliosis, Sprengel	3
Congenital heart disease	11
Ears—low set	7
Skin—café-au-lait spots	1
Toe syndactyly	2
At least one anomaly	60

while platelet counts are normal or increased. The patients' erythrocytes have several characteristics which define them as 'fetal': macrocytosis, increased fetal Hb and fetal membrane antigen i, as well as fetal patterns of red cell enzymes.[4,6] The bone marrow shows normal cellularity with erythroid hypoplasia in 90% of cases, while the rest have normal or hyperplastic erythroid development. Serum erythropoietin is increased, and most patients do not have serum inhibitors of erythropoiesis. Peripheral blood lymphocyte and bone marrow chromosomes are usually normal.

Cellular inhibition of erythropoiesis has been proposed but not confirmed as the pathophysiology of Diamond-Blackfan anaemia. Hoffman and co-workers found that the peripheral blood lymphocytes of 6 transfusion-dependent patients inhibited *in vitro* erythroid colony formation from normal bone marrow cells.[7] Steinberg and co-workers also observed suppressor lymphocytes in 2 patients.[8] However, Nathan and co-workers and Freedman and co-workers were unable to confirm this finding in a variety of patients.[9,10,11] Those patients who had inhibitory cells in the study of Hoffman had received multiple transfusions, and had presumably been sensitised to antigens which happened to be present in the normal bone marrows which were used in the experiments.[7] A similar problem has been reported in patients with acquired aplastic anaemia.[12]

The abnormality in Diamond-Blackfan anaemia appears to be in the erythroid stem cell. Null lymphocytes purified from peripheral blood contain erythroid progenitors, while T-lymphocytes produce soluble factors which stimulate *in vitro* colony formation from the null cell population.[13] Nathan and co-workers mixed null and T-cells from normal subjects with those from patients with Diamond-Blackfan anaemia.[14] T-cells from patients not only failed to inhibit, but actually stimulated erythroid colony formation from normal null cells. In contrast, null cells from patients failed to respond to normal T-cells. In other studies, *in vitro* erythroid colony formation from the bone marrow cells of patients with Diamond-Blackfan anaemia was decreased, and required unusually high levels of added erythropoietin. Thus the erythroid stem cell may have an abnormal response to the usual stimuli for erythropoiesis.

Patients with Diamond-Blackfan anaemia were initially treated by giving blood transfusions, and they died when these were stopped. Transfusions are still needed, at the time of diagnosis, and for about 20% of patients who do not respond to other forms of treatment. The current recommendation is that complete red cell typing be performed to reduce the possibility of sensitisation to red cell antigens. Frozen, washed, packed red cells should be used if possible. Hb should be kept above 6 g/dl, with transfusions every 4 or 6 weeks. The main complication from multiple transfusions is iron overload; this may be controlled with chelating agents.[15]

Administration of corticosteroids leads to a response in approximately three-quarters of the patients. Initial treatment is with prednisone, 2 mg/kg per day (given in three or four doses). Reticulocytes appear between one and 3 weeks later. Daily treatment is continued until Hb reaches 10 g/dl. The corticosteroid dose is then tapered, and treatment is given on alternate days. Most patients require from 1 to 40 mg prednisone on the treatment days, given as a single dose in the morning. A few puzzling patients respond to corticosteroids initially, but then fail to maintain erythropoiesis on doses that are less than toxic. Occasionally, a combination of low-dose corticosteroids plus androgens has been useful. One patient was engrafted successfully with a bone marrow transplant, but unfortunately died from pulmonary complications caused by haemosiderosis.[16] 20 to 30% of patients were reported to have spontaneous remissions from one to 16 years after the onset of their anaemia. The erythrocytes of most patients in 'remission', either corticosteroid-dependent or spontaneous, have fetal characteristics (see above), indicating that the patients are not cured of their underlying disease.

The reported mortality rate is approximately 15%, although it is undoubtedly higher. Most deaths were from complications of chronic transfusions and haemosiderosis—such as heart disease or pulmonary infections.

Recent reports have drawn attention to possible malignant complications. One patient developed hepatocellular carcinoma in a haemosiderotic liver.[17] Two patients died with acute myelogenous leukaemia as adults. One had been in a spontaneous remission from ages 16 to 32, after several hundreds of transfusions in childhood.[18] The other had received irradiation to long bones and thymus as a child, as well as many transfusions (L. K. Diamond, unpublished observations). One patient died with acute promyelocytic leukaemia; she had been transfusion-dependent, and had failed to respond to corticosteroids, cyclophosphamide, and androgens in the years before the leukaemia.[19] One child did respond to treatment for acute lymphocytic leukaemia.[20] The interrelations of an abnormal erythroid stem cell, haemosiderosis, and immunosuppressive drugs, form a currently unresolved matter of concern.

Acquired red cell aplasia: transient erythroblastopenia of childhood

Temporary anaemia, reticulocytopenia, and marrow erythroblastopenia have been reported in approximately 60 previously normal children (M. Link and B. P. Alter, unpublished observations). Transient reticulocytopenia is common in children with haemolytic disorders—such as hereditary spherocytosis or sickle cell disease—in whom anaemia is soon detected because of the short life span of the erythrocytes. The term 'transient erythroblastopenia of childhood' is restricted to those children who have no underlying haematological disease, and who recover. In Table 2 patients with this acquired and temporary anaemia are compared with those who have the constitutional permanent variety, Diamond-Blackfan anaemia. In the transient cases, a viral illness was usually noted 2 weeks to 2 months before diagnosis. All patients were between one month and 6 years of age, but 80% were between one and 4 years. The only unusual physical finding was pallor.

The blood shows anaemia, reticulocyte counts <1%, normal white blood counts, and normal or increased platelet counts (M. Link and B. P. Alter, unpublished observations). Red cell antibody tests are negative. Wang and Mentzer observed that patients with transient erythroblastopenia could be distinguished from those with Diamond-Blackfan anaemia because the erythrocytes of the former were adult in several features.[6] This distinction is useful at the time of diagnosis. However, patients with transient erythroblastopenia do produce erythrocytes with fetal characteristics during their recovery phase. This temporary fetal erythropoiesis resembles the chronic state of patients with Diamond-Blackfan anaemia (M. Link and B. P. Alter, unpublished observations). In transient erythroblastopenia, the bone marrow shows erythroid hypoplasia. Marrow culture *in vitro* did lead to normal erythroid colony formation in one study (B. J. Clarke *et al.*, unpublished observations); the erythroid cells which developed *in vitro* produced raised levels of fetal Hb. Recently, some patients with transient erythroblastopenia of childhood were found to have an IgG component in their sera which inhibits the growth of erythroid colonies in culture.[21]

Table 2 *Comparison of childhood red cell aplasias*

	Diamond–Blackfan anaemia	*Transient erythroblastopenia of childhood*
Number of reported cases	>200	60
Age at diagnosis	90%, <1 year	80%, 1 to 4 years
Aetiology	Constitutional	Acquired
Antecedent history	None	Viral illness
Physical examination	30%, abnormal (Table 1)	Normal
Laboratory		
Hb	2–4 g/dl	3–9 g/dl
White blood count	Normal	Normal
Platelet count $>400 \times 10^9$/l	80%	100%
MCV increased		
At diagnosis	30%	0%
After recovery	100%	90%
During remission	100%	0%
Hb F increased		
At diagnosis	100%	0%
After recovery	100%	100%
During remission	85%	0%
i antigen		
At diagnosis	100%	0%
After recovery	100%	60%
During remission	90%	0%

Adapted from Alter[4].

Recovery is usually apparent within one month of diagnosis. Many children require a single transfusion because of the anaemia. Corticosteroids have been used in cases in which the diagnosis was thought to be Diamond-Blackfan anaemia. However, permanence of recovery after corticosteroids were stopped led to the correct diagnosis. The transient fetal erythropoiesis noted above is independent of the mode of therapy.

Transient erythroblastopenia probably occurs frequently, as reticulocytopenia often accompanies viral illnesses. The disorder is only detected if Hb drops to symptomatic levels, or if blood counts are obtained before the onset of anaemia. Many children recover without any specific treatment, and anaemia does not usually recur with subsequent viral infections.

Acquired red cell aplasia: adult pure red cell aplasia

Many adults and a few adolescents have been reported to have developed pure red cell aplasia. The adult diseases have been reviewed extensively by Krantz and co-workers, and should be considered in paediatric cases.[22,23,24,25] Half the adults had an associated thymoma; the male:female ratio is 1:2 in those with, and 2:1 in those without this association. A few patients had malignancies. Children have been reported who developed red cell aplasia during treatment for leukaemia.[26] Many of the adults have had laboratory evidence of autoimmune disorders.

The anaemia is normochromic and normocytic, with reticulocytopenia. White blood counts and platelet counts are normal or decreased. Bone marrows show normal cellularity and erythroid hypoplasia. Autoimmune manifestations have included antibodies to red cells, smooth muscle, and intrinsic factor, as well as antinuclear antibody and paraproteins. Soluble inhibitors of erythropoiesis have been demonstrated in the IgG fraction from several patients. These antibodies have inhibited *in vitro* heme synthesis, and *in vitro* erythroid colony formation from normal marrow precursors. In some cases, the inhibitors were cytolytic to erythroblasts. A few patients had antibodies to erythropoietin.

The main treatment is transfusion. Thymectomy may be helpful in those with a thymoma. Splenectomy has had limited success. Chemotherapy has included corticosteroids, cyclophosphamide, azathioprine, and 6-mercaptopurine, and one, or a combination of these, has occasionally led to a remission. However, a guarded prognosis must be given to patients with the adult form of acquired red cell aplasia.

Conclusions

The form of red cell aplasia with the best prognosis is transient erythroblastopenia of childhood. Children acquire this anaemia rapidly, due to transient cessation of erythropoiesis. They also recover rapidly and apparently permanently. They exhibit temporary fetal erythropoiesis, similar to that seen in any type of stress erythropoiesis, but this disappears. Specific studies of erythropoiesis are incomplete because of the rapid course and rarity of patients. Although soluble or cellular inhibitors of erythropoiesis may be involved in some cases, the most likely aetiology is a failure of development of erythroid progenitors.

In adult pure red cell aplasia the disorder is long-lasting although there have been recoveries. Soluble inhibitors of various levels of erythropoiesis have been detected routinely. The erythroid progenitor cells themselves are apparently normal.

Constitutional red cell aplasia is apparently due to an abnormality in the erythroid stem cell itself. Most studies have failed to demonstrate soluble or cellular inhibitors of erythropiesis. Treatment with corticosteroids leads to a partial correction of the erythropoietic defect, perhaps by improving the interaction of erythropoietin with erythropoietin-responsive stem cells. Further studies are required to define the abnormality more specifically. Meanwhile, patients with red cell aplasia of any except the most transient variety must be followed up because of the possibility of belated haematopoietic developments.

A better deal for newborns with congenital heart disease

Despite the great strides made in management of heart diseases in children during the last 25 years, these still account for more deaths in infancy than all other congenital anomalies put together.[1,2] Furthermore in population studies on necropsy, it has repeatedly been shown that of deaths certified as due to congenital heart disease, about two-thirds were within the first year of life and about half of these were during the first month.[3] Population necropsy studies tend to present a gloomier prognosis than those based on diagnosis in life as well death. Nevertheless, in a study of the latter type carried out as recently as 1968–72, it was shown that, even when patients with severe associated congenital lesions were excluded, only 61% of infants with congenital heart disease survived the first year.[4] Effective prevention of congenital heart disease seems unlikely to emerge within the next decade, so that any policy designed to reduce death and disability from congenital heart disease must at present be focused on management during the early months of life. The paper by Izukawa *et al.*[5] (page 281) documents in a heartening manner the improvement in life expectancy that has occurred in newborns with structural heart disease in the last decade treated at their hospital, which acts as a referral centre for a large part of Canada.

In a number of committee reports on resources for management of heart disease in children, the principle has been accepted that in order to provide optimal standards of care, a limited number of specialist centres are required.[6,7,8,9] A revised report of the Joint Cardiology Committee is about to be published, taking the same view. This annotation will summarise the evidence supporting this view, and argue that in order to provide the best service for newborn babies with congenital heart disease, it is necessary to think in terms of creation of supraregional centres specialising in the care not just of newborns, but also of infants.

The reasons for the improvement in survival of newborns from Toronto[5] are, in brief, experience and expertise. While these do not always go together, they usually do. Particularly strong evidence for this assertion comes from a study carried out in London during the period 1969–71 of centres treating infants with congenital heart disease.[10] 13 such centres were identified as being involved in infant cardiac catheterisation and surgery; 2 of these performed 69% of all cardiac catheterisations and 76% of all operations. The combined operative survival for infants from the 2 centres was 72%, whereas the corresponding figure for the remaining 11 was 54% ($P<0 \cdot 001$). Furthermore, patients in the 2 centres were less likely to die at cardiac catheterisation, and more likely to have a corrective than a palliative operation. And this was despite the fact that both centres were seeing a population of infants with more serious congenital heart disease than were the others. So expertise is fundamental, but experience and therefore size cannot be ignored in planning cardiological services.

The incidence and severity of congenital heart defects is similar in America and England.[11,12] Therefore the size of the British problem can be defined very precisely from the New England Regional Infant Cardiac Program.[13] Case finding in that study[14] is almost certainly higher than that from any comparable British study. In New England there is a mixture of units, some aggressive and some more conservative in their management, much as there is in this country, so that projections of work load from their experience are probably quite reasonable for the UK.

The number of live births in England and Wales in 1974 was 603 140. A survey of 16 centres in England and Wales carrying out infant cardiac catheterisations showed that 47% of these were in neonates.[15] To these facts are added the following from the New England study:[4,13,14]

(1) The incidence of heart disease presenting in infancy and requiring cardiac catheterisation (2·7 per 1000) (D. C. Fyler, 1978, personal communication).

(2) The proportion of infants catheterised requiring operation in infancy (58%).

(3) The proportion of infants with severe associated anomalies precluding cardiac surgical intervention (10%).

From these figures it appears that each year 1470 (29·4 per million population) infant cardiac catheterisations and 850 infant operations can be expected from England and Wales. About 425 (8·5 per million) of these operations would be open heart ones.

The number of neonatal catheterisations is a very reliable indicator of patients referred, since essentially all catheterisations in this age range are emergencies, carried out in seriously ill babies. This number, predicted from the above figures, is 690 (13·8 per million) per annum for England and Wales. In the British survey,[15] 16 major centres reported an average of 365 neonatal catheterisations per year (1971–75). One large centre reported a further 54, too late for inclusion, but it is difficult to believe that the overall total from every centre in England and Wales could exceed 500 per annum. This leaves the total figure still 190 short of the prediction. This large shortfall can hardly be accounted for by the fall in birth rate, particularly as the total number of catheterisations performed did not change during the survey period. Nor does it seem likely that the problem lies in applying American figures to British patients. The possibility must be faced that about 25% of neonates with congenital heart disease in this country are still being neither adequately investigated nor treated. Why should this be? The most likely answer is that there is insufficient awareness of the possibilities of effective, curative treatment in specialist centres.

Let us leave aside the question of shortfall, and assume that there is none for the purpose of determining how many specialist centres are required. Successful management of infants with serious congenital heart disease is a matter of highly coordinated team work involving technical staff, specially trained children's nurses, experts in anaesthetics, ventilation, radiology, and nephrology, as well as paediatric cardiologists and cardiac surgeons. At any level, lack of sufficient experience prejudices the outcome. It may well be that no centre in the UK has yet reached an optimal level of activity. However, a minimum is probably one infant open heart operation per week on average. Open heart surgery is chosen as the paradigm because it is the most demanding on personnel. To achieve the predicted requirements, only 8 centres in England and Wales would be necessary. However, two surgeons per centre are required to maintain 24-hour cover. Sharing the work load, each would only do one infant open heart operation a fortnight. Most surgeons would not regard this as adequate to maintain standards, so the optimal number of centres required in England and Wales is probably less than 8, particularly as these figures have been calculated for predicted rather than actual work load.

Supraregional centres along the lines proposed would not, of course, limit their activities to infants. If they were to do so, there would be an insufficient total volume of work, and what work there was would be of such complexity that it would make impossible demands on the personnel of such a unit. A much wider age range of patients would be treated.

This figure for the number of supraregional centres required is uncomfortably low, and specialisation of this order would undoubtedly introduce new problems. What are they, and would they outweigh the benefits?

The first disadvantage is of course that there would be a lot of travelling for the baby and relatives. This will never be a pleasant experience, but then neither is the unnecessary death of the baby. We (and doubtless others) have found that it is possible for a young infant to suffer several cardiac arrests outside the UK, and yet to survive a long air flight and corrective surgery in this country. This illustrates graphically that transport need not be hazardous provided that the means to maintain thermal, fluid, and acid-base balance, together with ventilation (if necessary), are initiated before the journey.

At the moment, such care is undertaken by the referring nonspecialist hospital. In the future, the responsibility for this kind of action may come to rest with the specialist centres, along the lines developed by general neonatal intensive care units.[16,17] But because of the far greater distances, this would place demands upon the medical and nursing personnel in the specialist centres that would be extremely heavy, and certainly beyond the present capabilities of any unit of this type in the country.

Of particular concern, as so many of these emergencies occur in the first few days of life, is that the baby may be transported, but the mother is not. This inevitably impairs primary bonding and establishment of breast feeding. This is perhaps particularly unfortunate if the physical condition of the baby turns out not to be serious. These problems would, in my view, be greatly alleviated by a 2-pronged strategy. Firstly, paediatric cardiologists would have to take more seriously their educational role with regard to budding (or even not so budding) paediatricians and neonatologists, as these play such a vital role in screening for serious structural heart disease. This would not only reduce unnecessary referrals (which are in any case rare), but, more importantly, help to ensure earlier referral of serious heart disease before the baby's condition becomes critical. Secondly, mothers could be encouraged more often to accompany their babies (particularly if they have no other children) and would be actively helped to do so, even if it meant extra medical care for the mother.

Cardiac catheterisation and surgery are not cheap when viewed in isolation, but there can hardly be another specialty where such sick individuals are so completely restored to normality for such a long time. So the cost-benefit ratio, insofar as this can be quantified, is probably low compared with many other widely performed procedures. All in all, the benefits of supraregionalisation of infant cardiac care far outweigh the disadvantages, provided that the latter are minimised along the lines suggested.

It is true that in 1979, now that some lesions can be repaired in infancy with an immediate survival of better than 95% in a few centres, that the residual problems are becoming more and more concentrated in the first month of life.[18] But for three reasons, my view is that it would be a mistake at this stage to create neonatal rather than infant supraregional centres. Firstly, the number would be too small. Secondly, open heart surgery in later infancy is still far from routine even in specialist centres. Thirdly, some of the numerically most important conditions causing serious cardiac disability and death in infancy do not normally present until the 2nd and 3rd month of life, notably ventricular septal defect. Since it has been clearly shown that in certain centres, primary closure of the defect in infants with intractable cardiac failure carries a lower early and late mortality than banding of the pulmonary artery,[19,20] there seems to be a good argument for the creation of centres where such open heart approaches to treatment may become routine. At this time, only a few such hospitals in this country have established reputations in the field, so that recognising these as supraregional centres would not be difficult. The longer action along these lines is delayed, the more centres will become involved. Rationalisation could then become painful to the point at which it would never happen. The arguments put forward will perhaps have convinced even the sceptical that this would be a pity.

Diagnosis and management of folate deficiency in low birthweight infants

M. K. STRELLING, D. G. BLACKLEDGE, AND H. B. GOODALL

Department of Paediatrics, Plymouth General Hospital, and Department of Pathology, Ninewells Hospital

SUMMARY Significant folate deficiency in 14 out of 37 preterm infants of birthweights 2·0 kg or less was found to be reliably and most conveniently diagnosed by abnormal morphological changes in peripheral blood and confirmed by the response to folic acid. Deficiency appeared to be more common in light-for-dates infants including the smaller of twins. Neither the clinical status nor the levels of haemoglobin or erythrocyte folate was a reliable guide to the presence of megaloblastic erythropoiesis in the very young preterm infant. 100–200 μg folic acid a day, orally or IM, may be required to ensure an optimal haematological response, and this would be appropriate for therapeutic trial if the diagnosis is in doubt. This amount would also replenish tissue folate stores; larger doses are likely to exceed the requirements of small infants.

In an earlier paper (Strelling *et al.*, 1966) we drew attention to the vulnerability of premature infants to folate-responsive megaloblastic anaemia. The most appropriate dose of folic acid for the treatment of affected infants is however unknown. The effect of varying amounts of folic acid on 19 infants is reported, in whom the morphology of the peripheral blood was either frankly megaloblastic or highly suggestive of such change. The diagnosis of folate deficiency in the very young low birthweight infant and the value of a therapeutic trial with small 'physiological' amounts of folic acid are also considered.

Materials and methods

The infants with observed or suspected megaloblastosis were discovered during the course of an investigation into the folate status of approximately 100 infants between birth and 12 months. 37 of these fulfilled the following criteria: (a) gestation <37 completed weeks*, (b) birthweight 2·0 kg or less*, (c) unaffected by a major congenital abnormality or haemolytic disease. They were as far as possible consecutive admissions to a special care baby unit.

24 were term (38–42 completed weeks), normal, singleton infants from uncomplicated 1st or 2nd pregnancies weighing at least 3·0 kg at birth selected as controls with informed parental co-operation. All these infants thrived.

None of the mothers in either group of infants had been folate-deficient or had received folic acid supplements during pregnancy.

Feeding. The preterm infants were fed evaporated milk (Carnation) changing to full-cream dried milks when their weights had reached 2·5 kg. From the 3rd week they were given 22 mg elemental iron in 4 ml sodium iron edetate (Sytron, Parke-Davis) and 7 drops of a multivitamin preparation not containing folic acid (Protovite, Roche) each day. All except 2 control infants who were breast fed received dried milk feeds. The milks were sterilised by autoclaving after reconstitution.

Investigations. Blood was taken by heel prick just after birth, repeated at 2 to 4 weeks, and at least twice during weeks 5 to 10. Further samples were

*One infant of 37 weeks and one of birthweight 2·06 kg with suspected megaloblastosis were included.

taken during weeks 11 to 20 and between months 6 and 12. The following examinations were made: Hb, MCHC, reticulocytes, PCV, and films. Buffy coat smears were taken from microhaematocrit preparations spun relatively slowly (750 rev/min) for 5 minutes.

Assays of whole-blood folate (*L. casei*) were made on duplicate samples of 50 µl blood using the method described previously (Strelling *et al.*, 1966), red-cell folate being calculated from the haematocrit.

Abnormal haemopoiesis was assessed on blood and buffy coat smears as: (1) *megaloblastic*; the presence of megaloblasts or transitional megaloblasts with eosinophilic or polychromatophilic cytoplasm, or (2) *suspected megaloblastic*; orthochromatic oval macrocytes, macronormoblasts, and hypersegmented neutrophils. Marrow biopsies were not taken.

Folic acid treatment. Folic acid was given daily as follows: (1) 5 mg IM (6 infants) and orally (1 infant), (2) 1–2 mg orally (4 infants), (3) 60 µg IM (2 infants) or 50 µg orally (2 infants), and (4) 15–120 µg IM initially, the amount being increased every few days depending on the haematological response (4 infants).

As only 5 mg tablets of folic acid were available both 1 mg and 50 µg tablets of folic acid were prepared commercially. A parenteral folic acid solution containing 15 mg/ml (Folvite, Lederle) was appropriately diluted immediately before each IM injection.

The haemopoietic response was assessed on the reticulocyte count, blood films, and buffy coat smears.

Birthweight/gestation centiles. These are from the data of (1) Thomson *et al.* (1968) for infants born after 31 completed weeks, allowing for sex and parity, (2) Babson *et al.* (1970) for infants born between 28 and 31 completed weeks.

Results

Findings in low birthweight infants. Megaloblastosis was observed in 19 of the preterm infants with birthweights of 2 kg or less. Data on these infants are shown in Table 1. In 14 the diagnosis was confirmed by the haematological response to treatment with folic acid, but this was suboptimal in 4 (Cases 15–18) and was not assessed in one (Case 19). The remaining 18 low birthweight infants showed no morphological evidence of folate deficiency, and none of the 6 who received a trial of folic acid showed any haematological effect. Data on these infants and the controls are shown in Table 2.

Nine (64%) of the confirmed megaloblastic group had birthweights below the 10th centile compared with 5 (28%) of the normoblastic group. In all the 45 infants who were below 37 weeks' gestation irrespective of birthweight, there were significantly more who were light-for-dates in the megaloblastic group ($P<0\cdot05$).

Hb was invariably below 10 g/dl in the megaloblastic infants at diagnosis but it was also at this level in 13 of the 18 normoblastic infants. The mean difference in Hb at average age 7 weeks was 1·1 g/dl, values in the megaloblastic group being significantly lower ($P<0\cdot05$, Table 2).

Erythrocyte folate levels in 22 of the 37 low birthweight infants at average age 7 weeks were below those in controls of comparable postnatal age ($P<0\cdot05$, Table 2). Values in 3 infants with confirmed or suspected megaloblastosis and in 5 of the normoblastic low birthweight group were nevertheless within the control range.

None of the control infants at any time and no low birthweight infant over 12 weeks showed any cytological evidence of folate deficiency on peripheral blood examination. Three of the normoblastic low birthweight infants who did not receive folic acid had erythrocyte folate levels <100 µg/l at 6 months.

The condition of no infant caused undue concern when morphological evidence of folate deficiency was found, although in 4 there had been previous clinically mild infections of the urinary or respiratory tracts.

Serum vitamin B12 values (*Lactobacillus leichmanni*) in 5 low birthweight infants were 150–335 ng/l (normal 160–950 ng/l).

Treatment with folic acid.

Standard doses (1–5 mg daily)

An unequivocal response occurred in all 6 infants given 5 mg folic acid daily IM (Cases 1–6) and in 3 of the 4 given 1 or 2 mg orally (Cases 7–9). Blood films and buffy coat smears examined between days 3 and 7 showed normoblastic transformation and a pronounced increase in polychromatophilic erythrocytes. Reticulocytes were often slightly increased before treatment but a definite subsequent rise was nevertheless demonstrable. Enlargement of spleen and/or liver was noted in several infants after treatment with folic acid; the reason for this was not clear.

The haematological response was suboptimal in Case 15 (5 mg/day orally) and was not assessed in Case 19 (2 mg/day orally).

Whole-blood folate was estimated in 4 megaloblastic infants receiving 5 mg/day folic acid IM and

in 12 further infants of birthweights 2·0–3·0 kg receiving 5 or 10 mg/day orally. Values >1000 µg/l were invariably found. These were not assayed precisely in this high range but would almost certainly have produced red-cell folate values well above normal. Erythrocyte folate assayed after stopping treatment declined slowly; at an average age of 7 weeks later the mean value in 11 infants was 828 µg/l (405–1406 µg/l).

Unchanging small doses

Both infants given 60 µg/day of folic acid IM (Cases 12 and 13) and one of the 2 given 50 µg/day orally (Case 14) showed a brisk normoblastic and reticulocyte response; erythrocyte folate was not measured. The response to 50 µg/day of folic acid orally in the 4th infant (Case 18) was difficult to assess as the abnormal morphology had improved spontaneously in the week before treatment when the reticulocytes were 6%.

Increasing small doses

In an attempt to find a minimum effective therapeutic dose, 4 infants were given progressive increments of folic acid while the morphology and red-cell folate were monitored. Details are given below.

Case reports

Case 10 (Figure). A baby boy, birthweight 1·56 kg, 32 weeks' gestation. At 7 weeks Hb 8·1 g/dl, PCV 22, and erythrocyte folate 150 µg/l. Transitional megaloblasts were noted in buffy coat smears and, 2 days later, true megaloblasts. The reticulocytes had begun to rise (7%) before folic acid was started.

15 µg folic acid IM for 3 days and 60 µg IM for 2 days produced no haematological response and megaloblasts persisted. Two doses of 120 µg/day IM were followed by an increase in polychromatic erythrocytes, and these and normoblasts were smaller. Megaloblasts disappeared and reticulocytes rose to 10% although the erythrocyte folate fell slightly to 122 µg/l. This response continued for a further 7 days with a peak reticulocytosis of 14% after 10 × 120 µg folic acid IM when the erythrocyte folate was 530 µg/l. The intensity of response then diminished gradually despite increased dosage.

Comment

A haematological response and a rise in erythrocyte folate was obtained with 120 µg/day folic acid IM.

Case 11. A baby boy, birthweight 1·78 kg (<10th centile), gestation 35 weeks. At 6 weeks Hb 9·1 g/dl, PCV 28, reticulocytes 3%. Transitional megaloblasts and slightly increased polychromasia on blood films.

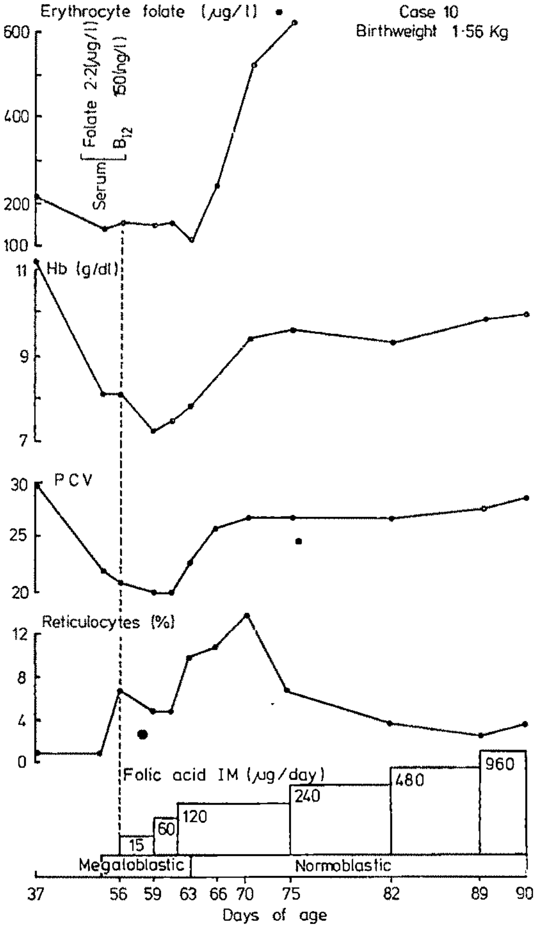

Figure *Treatment of megaloblastic anaemia in a preterm infant with increasing small doses of folic acid.*

Erythrocyte folate 168 µg/l. Folic acid 60 µg/day IM produced a moderate normoblastic response with reticulocytes of 5% on day 2 rising to 14% on day 7.

Erythrocyte folate was 167 µg/l on day 6 but fell to 108 µg/l on day 15 so the folic acid was increased to 120 µg/day IM. The reticulocytes remained raised until 6 weeks after beginning treatment.

Comment

Although a good haematological response occurred on 60 µg/day folic acid IM the erythrocyte folate declined; 120 µg/day might have been the appropriate dose.

Case 16. A baby girl, birthweight 2·06 kg, gestation 33 weeks. At 7 weeks folate deficiency was suspected, Hb 9·1 g/dl, PCV 25, reticulocytes 3%. Erythrocyte folate was low at 64 μg/l. A week later the morphology was less abnormal, Hb 9·9 g/dl, reticulocytes 5%, and erythrocyte folate 88 μg/l. Folic acid 60 μg/day was given IM and although polychromatic cells and reticulocytes increased slightly (7%), the response was not definite. As the erythrocyte folate had fallen to 40 μg/l on day 7, folic acid was increased to 120 μg/day IM.

Case 17. A baby girl, birthweight 1·35 kg, gestation 31 weeks. At 11 weeks folate deficiency was suspected on blood films which showed pronounced neutrophil hypersegmentation. Hb 10 g/dl, PCV 30, reticulocytes 2%. Erythrocyte folate was low at 67 μg/l. A week later without treatment the morphology was less abnormal, Hb 9·6 g/dl, PCV 27, reticulocytes 4%. Erythrocyte folate had risen to 140 μg/l. There was a slight haematological response after 3 days of treatment with folic acid 120 μg/day IM. As the erythrocyte folate had fallen to 86 μg/l the dose was increased to 240 μg/day IM for a further 3 days.

Comment

Morphological abnormalities improved in Cases 16 and 17 before treatment. The haematological response to 60 μg/day IM (Case 16) or to 120 μg/day IM (Case 17) was suboptimal. Erythrocyte folate fell in both infants, suggesting these amounts fell short of requirements.

Discussion

Diagnosis. Megaloblastic haemopoiesis may be overlooked in small infants. Clinical pointers to severe folate insufficiency which might have been expected—such as pallor, poor feeding, slow weight gain (Gandy and Jacobson, 1977), or severe infections (Gray and Butler, 1965)—were generally absent when the diagnosis was made and earlier infections in a minority of infants had been clinically mild. Neither Hb nor erythrocyte folate level was found to be a reliable guide to megaloblastic haemopoiesis. No affected infant had Hb >10 g/dl but only a few were significantly anaemic for infants of comparable birthweights and ages (Lundstrom *et al.*, 1977). Megaloblastosis however developed at an average age of 7 weeks when the effect of folate deficiency on Hb level is likely to be masked by such major physiological variables as red-cell mass at birth, postnatal depression of erythropoiesis, and rate of growth. The erythrocyte folate often fell during the 2nd and 3rd months to subnormal levels in both normoblastic and megaloblastic infants <2 kg birthweight, but values did not necessarily reflect the true severity of folate depletion. These were within the range found in term healthy controls (110–655 μg/l) in 2 infants with confirmed and one with suspected megaloblastosis, presumably due to the survival of erythrocytes formed during the perinatal period of relative folate affluence.

On the other hand, a clinical feature not previously described is a possible relationship between low birthweight for gestational age and the subsequent development of megaloblastic anaemia, for there was an undue proportion of preterm infants who were light-for-dates (<10th centile) among the megaloblastic group. Moreover, in 2 twin pregnancies only the smaller of each pair was affected. The reason for this is uncertain: limited fetal acquisition of folate or relatively rapid postnatal growth (Gairdner and Pearson, 1971) may well be contributory factors. An association between erythroblastosis, rate of weight gain, and folate insufficiency in infants up to one year has been reported (Gandy and Jacobson, 1977). While we were unable to find megaloblastic haemopoiesis in a group of erythroblastotic infants studied from birth, there was a haematological response after folic acid treatment in 2 affected preterm infants who had become severely anaemic at 3 and 5 weeks (Strelling, 1977).

The mainstay of diagnosis of folate deficiency was abnormal morphology using the buffy layer of capillary blood centrifuged slowly to concentrate abnormal cells, particularly the megaloblasts. While morphological abnormalities were sometimes shortlived and were not found in any case beyond 12 weeks, a search for them appears essential to the evaluation of the folate status of very young preterm infants.

Prevention. Whether folate insufficiency affects the somatic growth or neurological development of preterm infants is unknown. Lack of the vitamin limits the synthesis of thymidylate, a necessary precursor of DNA, megaloblastosis representing a stage at which DNA replication has become deranged (Hoffbrand *et al.*, 1976). Deficiency not severe enough to produce megaloblastosis may nevertheless impair growth, as shown in erythroblastotic infants by Gandy and Jacobson (1977). Dallman (1974a) estimated that preterm infants need 50–70 μg (25–35 μg/100 kcal) of folate a day. Neither the newer ready-to-feed proprietary milks (3·2–3·5 μg/100 ml*) nor fresh human milk (average 5·4 μg/100 ml, Ford and Scott, 1968) is likely to supply more than 10–20 μg/day of folate to very low weight infants over the first 8 weeks. Evaporated milk given to the infants in this study may have provided even less, for such milk with a relatively small ascorbic acid content tends to lose heat-labile folate through sterilisation (Ford and Scott, 1968). As preterm infants are vulnerable to deficiency during a period of rapid growth and cell replication, we would continue to advocate that folic acid supplements of about 50 µg/day be given to those under 2 kg for the first 3 months to ensure an ample supply for growth and development.

---

*Manufacturers' reports.

Treatment. There is little information on the optimal amount of folic acid required for the treatment of preterm infants with megaloblastic anaemia. Recommended doses generally vary between 500 µg (Dallman, 1974b) and 2–5 mg (Smith, 1972; Pearson, 1975) a day, although Willoughby (1977) suggests that 200 µg may be enough in uncomplicated cases.

We found that 5 or 10 mg/day folic acid either orally or IM produced high blood folate levels and was clearly in excess of the requirements of small infants; an oral dose of 1 or 2 mg gave an equally good haematological response.

Daily doses of between 50 µg orally and 120 µg IM also produced an optimal haematological response in 5 out of 8 infants tested. The response to the same dose in the other 3 was suboptimal, possibly because morphological abnormalities had improved and reticulocytes begun to rise before treatment was started.

Erythrocyte folate was monitored in 4 of the 8 infants given small doses of folic acid. 60 µg/day IM was accompanied by falling levels in 3 infants, in one of whom increasing the amount to 120 µg produced a satisfactory rise. The same dose was associated with a drop in folate in the 4th infant.

Hence, although an excellent haematological response may follow as little as 50 µg/day folic acid, this amount is unlikely to meet the demands of increased haemopoiesis and, at the same time, replenish the infant's stores of folate. Needs may also vary and a full haemopoietic response may not always occur on this amount. Therefore the optimal therapeutic dose of folic acid is probably in the region of 100–200 µg/day orally or IM. Crystalline folic acid (pteroylmonoglutamic acid) was well absorbed orally in the small infants but suitable small dose oral or parenteral preparations are not readily available in the UK.

It may be considered whether treatment with excess folic acid could be potentially harmful, especially to the immature brain. Although folic acid has potent convulsive effects in experimental animals when injected directly into CSF or the brain (Hommes and Obbens, 1972) there appears to be an efficient homeostatic mechanism in the blood–brain barrier which helps maintain CSF and probably brain levels of folate within relatively narrow limits (Spector and Lorenzo, 1975). The main objection to the use of excess folic acid appears to be if vitamin B12 deficiency were present. A suboptimal haematological response may then follow treatment with large doses of folic acid and there is at least a theoretical risk that such treatment may precipitate central nervous system damage. Thus brain damage associated with congenital vitamin B12 deficiency has been reported (Pearson *et al.*, 1964; McNicholl and Egan, 1968); 4 of these infants with congenital deficiency of intrinsic factor had been treated with large amounts of folic acid (Strelling, 1969). There is insufficient information concerning the vitamin B12 status of preterm infants. 14 out of 24 such infants in one report (Pathak and Godwin, 1972) had subnormal serum levels although values in 5 low weight infants in this study were in the low normal range.

It may be concluded that significant folate deficiency in infants <2 kg birthweight may be reliably and most conveniently diagnosed on abnormal morphological changes in peripheral blood and adequately treated with 100–200 µg/day folic acid, orally or IM. The haematological response to this amount would also serve as a therapeutic trial when the diagnosis is in doubt.

We thank Professor J. R. Ashford, Department of Mathematics, Exeter University, and Professor J. R. T. Colley, Department of Community Health, Bristol University for help with statistical analyses, and Wyeth Laboratories for financial support.

New technique for servo-control of arterial oxygen tension in preterm infants

I. R. BEDDIS, P. COLLINS, N. M. LEVY, S. GODFREY, AND M. SILVERMAN

Departments of Paediatrics and Neonatal Medicine, and Medical Physics, Hammersmith Hospital, London

SUMMARY Equipment has been developed for the servo-control of arterial oxygen tension in sick, newborn babies. Using an indwelling umbilical arterial oxygen electrode as sensor, the equipment successfully regulated the administration of oxygen to 12 newborn babies with respiratory distress syndrome, significantly improving the stability of arterial oxygen tension and lessening the duration of episodes of hypoxia and hyperoxia.

In recent years, the continuous monitoring of oxygen tension in sick, preterm babies has been made possible by the development of miniature polarographic electrodes. Arterial oxygen tension (Pa_{O_2}) can be measured using an umbilical catheter-tip electrode, or transcutaneously using a heated skin-surface electrode. Thus, the twin hazards of prolonged hypoxia (Stewart and Reynolds, 1974), and hyperoxia (Ashton *et al.*, 1953), can be avoided by manual adjustments to the fractional inspired oxygen concentration ($F_{I}O_2$) when Pa_{O_2} deviates from within safe limits.

When Pa_{O_2} is continuously monitored in sick, preterm babies, pronounced fluctuations can be seen to occur within short periods of time, although intermittent blood–gas analysis may indicate a steady state. Fluctuations may occur spontaneously, or result from routine nursing or other procedures (Speidel, 1978), and such changes in Pa_{O_2} together with alterations in heart rate and blood pressure may be responsible for intracranial haemorrhage in some cases (Wigglesworth and Pape, 1978). Correction of these fluctuations by the manual adjustment of $F_{I}O_2$ requires constant, time-consuming observation. It seemed obvious to try to automate this procedure and we describe the application of a prototype machine for the automatic control of Pa_{O_2} in sick, preterm babies.

Patients and methods

12 preterm babies with respiratory distress syndrome were studied in the first week of life. Their birthweights ranged between 760 and 2260 g (mean 1640) with gestational ages between 26 and 34 weeks (mean 31·3). The main items of equipment and their arrangement are shown in the Figure.

In each case, Pa_{O_2} and $F_{I}O_2$ were continuously monitored using an indwelling umbilical artery catheter-tip electrode (Searle) and an oxygen analyser (Hudson). The umbilical catheter was continuously flushed with dextrose/saline at a rate of 0·5 ml/hour. Its reading was checked at least 4-hourly by formal blood–gas analysis (I.L. 213 blood–gas analyser), and adjustments were made as necessary. The largest adjustment required during the study period was 1·6 kPa (12 mmHg).

The output of the Pa_{O_2} electrode was fed into the servo-control unit, the technical details of which are

presented in a separate paper (Collins *et al.*, 1979). At 1-min intervals, the reading was compared with the preset limits for Pao$_2$: lower limit 7·3 kPa (55 mmHg), upper limit 10·7 kPa (80 mmHg). If the Pao$_2$ was outside these limits, the servo-control unit adjusted the F_IO_2 (by means of a BOC air/oxygen mixer tap) by a single step of 5%. Thus, automatic adjustments of F_IO_2 were made at 1-min intervals if necessary. If 3 successive steps (i.e. 15% change in oxygen requirements) in either direction occurred, alarms were activated. Any defect developing in the function of the catheter-tip electrode would cause such successive steps in F_IO_2 to be made, and would therefore lead to activation of the alarms. Thus, the alarm would indicate failure of the equipment, disconnection of tubing supplying oxygen to the infant, or a change in the clinical state of the baby—such as a pneumothorax. In the event of mains failure, a preset F_IO_2 would continue to be provided and in an emergency any desired F_IO_2 could be obtained by pressing a button.

Using a multichannel chart recorder (Devices), Pao$_2$ and F_IO_2 were continuously recorded during the study. The first 9 babies were monitored during alternate 4- to 6-hour periods and the final 3 babies on random 4-hourly periods on servo-control or on manual control by the nurse, who adjusted the F_IO_2 if necessary. Oxygen was given according to clinical indications, by headbox or face mask or by endotracheal tube during the application of continuous positive airway pressure (CPAP) or during intermittent positive pressure ventilation (IPPV). The number of occasions during which the Pao$_2$ was outside the set limits and the duration of each occasion was calculated for each control period for different methods of oxygen administration to each baby. Paired *t* tests were used to determine the significance of differences between servo- and manual-control periods.

Results

The percentage of time spent outside the set limits of Pao$_2$ for each method of oxygen administration during servo-control and manual-control periods, is shown in the Table. The overall difference between servo-control and manual-control periods was highly significant ($t = 6{\cdot}36$; $P<0{\cdot}001$). The proportion of time during which Pao$_2$ was *below* the lower set limit was also significantly less on servo-control than on manual-control ($t = 4{\cdot}48$; $P<0{\cdot}001$). However, there was no significant difference between servo- and manual-control periods when the percentage of time *above* the upper set limits was compared ($t = 1{\cdot}87$; $P = 0{\cdot}08$).

In 11 of 12 babies the percentage of time outside the limits was less with the servo-control; in the 12th baby, the percentage was equal. Overall the Pao$_2$ was outside the set limits for 12·2% of the time when on servo-control and for 27·6% of the time when on manual-control.

The number of episodes during which the Pao$_2$ was <7·3 kPa and >10·7 kPa in the respective periods is also shown in the Table. The Pao$_2$ was below the set range on 263 occasions on servo-control and on 267 occasions on manual-control, and was above the upper set limit on 236 and 178 occasions respectively.

The mean duration of each episode *below* the lower limit on servo-control was 2·5 min and on manual-control it was 6·1 min. For the 12 patients, the difference in mean duration was highly significant ($t = 6{\cdot}51$; $P = <0{\cdot}001$). The mean duration of each episode *above* the upper limit on servo-

control was 1·7 min and on manual-control it was 4·7 min. The difference in mean duration was significant for the 12 patients ($t = 3 \cdot 85$; $P = 0 \cdot 002$).

Discussion

This study shows that the servo-control of arterial Po_2 is not only possible, but may also improve the stability of Pao_2 in the newborn. The equipment has been used successfully to control the administration of oxygen by IPPV, CPAP, or headbox so that long periods of hypoxia or hyperoxia could be prevented.

The whole servo-control system obviously relies on the accuracy of the continuous-reading Pao_2 electrode. So far, we have relied on umbilical arterial electrodes and we find that these give a satisfactory reading for a number of days, especially when flushed continuously at a low rate. There appears to be no reason why the system should not be used with a transcutaneous oxygen electrode. This would be particularly useful in the management of apnoea in preterm babies who often require a small increase in ambient oxygen, but who are particularly prone to episodes of hyperoxia with the attendant danger of retrolental fibroplasia. Whichever sensor is used, the need for regular, formal blood-gas analysis remains.

The range of Pao_2 which we selected was 7·3–10·7 kPa. The equipment had a 1-min sampling interval and produced 5% changes in fractional inspired oxygen concentration. 10% steps were used during initial trials, but wide swings in Pao_2 occurred. Neither the optimum sampling interval nor the size of stepwise changes in F_IO_2 has been determined. The fact that the number of episodes during which the Pao_2 was above the set limits was more on servo-control than on manual-control, suggests that there may be room for improvement. Work is in progress to determine the optimum characteristics of the system for different methods of oxygen administration and for different clinical conditions.

We feel that the apparatus has a useful role to play in the management of preterm infants with respiratory problems, avoiding the necessity for constant observation of a Pao_2 monitor and frequent manual adjustments of the fractional inspired oxygen concentration. The relative stability of Pao_2 achieved by the servo-control equipment seems certain to contribute to a reduction in morbidity in sick newborn babies.

This project was carried out with the support of the Wellcome Foundation and with the help and advice of Professor V. Dubowitz and the late Professor R. Oliver.

Structural heart disease in the newborn

Changing profile: comparison of 1975 with 1965

TERUO IZUKAWA, H. CONNOR MULHOLLAND, RICHARD D. ROWE,
DAVID H. COOK, KENNETH R. BLOOM, GEORGE A. TRUSLER,
WILLIAM G. WILLIAMS, AND GRAHAM W. CHANCE

The Hospital for Sick Children, Toronto, and University of Toronto Faculty of Medicine

SUMMARY The earlier detection and investigation of babies with congenital structural heart disease has resulted in earlier treatment and better management of these patients. In 1965, at the Hospital for Sick Children, Toronto, 121 cases were assessed and treated; by 1975 this figures had risen to 226 cases. Few changes were noted in the incidence of the 10 most common malformations, except for the obvious increase in the incidence of patent ductus arteriosus due to survival of increasingly premature infants. The sick cardiac neonate was referred earlier in 1975, studied with newer non-invasive investigations, and, according to the severity of symptoms and signs, was sent sooner to cardiac catheterisation. 80% of babies presenting with cyanosis survived the first month and 60% of babies with congestive heart failure survived. With better surgery and perioperative care, the survival rate in the first month after surgery rose from 37% in 1965 to 70% in 1975.

During the last decade there has been a wider recognition of the need for early referral and aggressive management of the newborn with cardiac malformation (Fyler, 1968; Varghese *et al.*, 1969). The increasing complexity of diagnostic procedures and support services, and the use of specialised surgical techniques (Mustard *et al.*, 1970; Edmunds *et al.*, 1972; Barratt-Boyes *et al.*, 1973), have resulted in a trend to regionalise these efforts (Fyler *et al.*, 1972; Nadas *et al.*, 1973; D. Cook *et al.*, 1978, unpublished data). Consequently, the numbers of patients admitted for this type of care have increased. This hospital reported that 211 neonates with congenital heart disease were assessed retrospectively for the period 1953–57 (Rowe and Cleary, 1960). By 1965, 121 neonates with heart malformation were being seen yearly.

In this paper the presenting features, type of anomaly, investigative techniques, and results of treatment in newborn patients with heart malformations seen in 1965 are compared with a prospective group of 226 such babies seen in 1975.

Materials and methods

Newborn infants seen with congenital heart malformations at this hospital in 1965 were analysed retrospectively by searching our data bank for infants with cardiac malformations; this data bank has been in operation since 1952 (Rose *et al.*, 1972).

Patients seen in 1975 were evaluated prospectively as neonates requiring cardiological consultation at the hospital. The newborn was first seen by a fellow in cardiology and shortly afterwards by a staff cardiologist. Preliminary investigations, apart from a physical examination, included blood-gas measurements, a chest *x*-ray, and an electrocardiogram. Echocardiograms were obtained in 128 of the 226 patients with structural heart disease. Results of the preliminary investigations and the recommended treatments were communicated to the appropriate unit staff. Further investigation by cardiac catheterisation and angiocardiography was performed after such consultations in 117 patients. Subsequent evaluations on the ward were performed by cardiologists usually daily, but more or less often according

to need. Follow-up after discharge, arranged through the referring physician, depended on the severity of the residual cardiac anomaly and the likelihood of future problems.

The final diagnosis was established at necropsy, surgery, cardiac catheterisation, or by clinical assessment only, in descending order of certainty. If multiple defects existed, the most important malformation was listed. A few broad categories of diagnosis were used. For example, hypoplastic left heart syndrome included aortic valve atresia, mitral valve atresia, and hypoplasia of all left heart structures without atresia. In the group hypoplastic right heart syndromes were lesions with hypoplasia of the right ventricle, particularly pulmonary atresia with intact ventricular septum and tricuspid valve atresia.

Premature infants with patent ductus arteriosus (PDA) were included in the group with structural heart disease because they were assessed according to their need for pharmacological or surgical treatment, as was the case with the other structural cardiac defects seen during 1975.

A second group of neonates with nonstructural heart disease are reported separately (Rowe *et al.*, 1978).

Results

Table 1 summarises the final diagnoses in the neonates with structural congenital heart disease. The 10 most common defects are listed in order of frequency in 1975 and compared with the prevalence in 1965. The obvious change between the two years is the pronounced increase in the number of PDA in 1975. Although the absolute number of patients with D-transposition of the great arteries (complete transposition of the great arteries) rose by half, from 18 to 27, this malformation was still in second place in 1975.

Table 1 *Incidence of common structural cardiac defects in neonates in 1965 and 1975*

Final diagnosis	*1965 (n=121)*		*1975 (n=226)*	
	No.	*%*	*No.*	*%*
Patent ductus arteriosus	10	8	69	31
D-transposition of the great arteries (complete transposition)	18	15	27	12
Hypoplastic left heart syndrome	11	9	21	9
Ventricular septal defect	19	16	25	11
Coarctation of aorta syndrome	10	8	16	7
Hypoplastic right heart syndrome	7	6	8	4
Tetralogy of Fallot	10	8	9	4
Aortic valve stenosis	1	1	5	2
Dextrocardia	8	7	6	3
Pulmonary valve stenosis	3	2	6	3
Others	24	20	34	15

The sex ratio in both groups shows there were more boys than girls, but this trend is diminishing (Table 2). A significant reduction in the birthweight of the neonate with structural heart disease seen in 1975 is apparent (Table 2). In 1975, the mean age at first assessment was 6·8 days compared with 8·3 days in 1965 (Table 2). If the patients with PDA as the principal defect are excluded, the mean age at first assessment in 1975 was 5·4 days. The patients with PDA were mainly premature infants who did not show evidence of the shunt until the second week of life.

A greater reduction is noted in the interval from initial clinical assessment to cardiac catheterisation between 1965 (5·3 days) and 1975 (1·8 days) in Table 3. The two main indications for cardiac catheterisation in the neonate are central cyanosis and congestive heart failure (Rowe, 1970). With increasing severity of these indications, there is a greater urgency to proceed to cardiac catheterisation. This urgency is reflected in the shorter time interval to cardiac catheterisation in 1975 compared with 1965 (Table 4).

NS = not significant at conventional (5%) level.

Approximately one-half of patients with structural heart disease were admitted for noncardiac reasons, the majority being premature infants with PDA who initially were admitted for prematurity alone or with respiratory distress, jaundice, or hypoglycaemia. The remaining patients, who were admitted with suspected cardiac malformations, showed cyanosis or congestive heart failure. The severity of the defects was not based on the presence or absence of heart failure or cyanosis, but rather on the basis of the patient undergoing cardiac catheterisation, surgery, or dying, as was done in the New England series (Fyler *et al.*, 1972). The survival rates of babies with or without cyanosis and/or congestive heart failure were higher in 1975 than in 1965. Statistically, the higher survival rate in patients with congestive heart failure was not significant (Table 5). The presence or absence of the patients with PDA in the category with cyanosis and/or congestive heart failure had little effect as the survival rate was greater in 1975 than in 1965 (Table 6).

The assessment of the acid-base status of the 10 groups is best appreciated by their division into three physiological groups as in Table 7, the first with central cyanosis or hypoxaemia, the second with pressure load, and the third with volume load. Examination of blood pH shows that acidosis occurs in all severe cases, but not necessarily in the mild. Acidosis is more severe in left heart obstruction with impaired peripheral perfusion (pH = 7·23). The highest value of Pco$_2$, hypercapnia, was in the volume load group (45 mmHg) and the lowest, hypocapnia, in the left heart obstruction group (25·2 mmHg). As expected, the maximum drop in Po$_2$ was in the hypoxaemia group (23·0 mmHg in D-transposition of the great arteries). The hyperoxic test indicates little rise in Po$_2$ in the hypoaemic group (23·0 to 24·7 mmHg mean).

In 1975, of 53 neonates undergoing cardiac surgery there were 37 (70%) survivors compared with a rate of 37% (13 of 35) in 1965 (Table 8). This increase in survivors undergoing surgery within the month in 1975 compared with 1965, was not due to increase in ligation of PDA. Despite the increase in this lesion, the number of ligations in 1975 in the first month of life was 5 with 4 surviving and 1 in 1965 who survived. The survival with Blalock-Hanlon procedure in D-transposition of the great arteries (complete transposition), was much improved in 1975. 16 neonates underwent this procedure under one month without a death in 1975; only 3 of 12 survived in 1965. The results with this operation accounted for part of the major improvement.

Table 6 *Survival of neonates with congenital structural heart defects (including and excluding patients with patent ductus arteriosus) and central cyanosis, congestive heart failure, or both, 1965 and 1975*

With medical treatment only, including patients with PDA, the survival rate in 1965 was 61% (54 out of 89) and in 1975 it was 75% (128 out of 170) ($\chi^2 = 5 \cdot 3$). If the patients with PDA are excluded, the survival rate was 58% (46 out of 80) in 1965 and 67% (72 out of 107) ($\chi^2 = 1 \cdot 8$) in 1975. The survival rate is higher in 1975 than in 1965, even with the PDA cases excluded, but the difference is not significant because of the smaller number of cases.

The management and prognosis of the neonate with heart disease may be influenced by the presence of extracardiac anomalies (Greenwood *et al.*, 1975). 26% of neonates with structural heart disease in 1975 had anomalies of systems other than the cardiovascular system. In 20% (45 out of 226) of the patients, admission was initiated because of the extracardiac anomalies. Mortality may have been influenced by the extracardiac anomalies in 28% (16 out of 57) with these additional defects.

Discussion

In 1960, the first report on congenital heart disease in the newborn from Toronto estimated the probable number of fatal cases there from the cases examined at the Hospital for Sick Children before death in the preceding 5 years. Fewer than half of these cases reached the hospital before death (Rowe and Cleary, 1960). In that period, 149 newborn babies with signs of heart disease survived the first month. The emphasis was on the difficulty of finding cases of congenital heart disease early and the need to separate severe from the less severe malformations. This was the preliminary to improving the survival of the seriously affected cases.

By 1965 the annual case load of structural heart disease was 121 patients. There were 13 survivors over a month postoperatively of 35 undergoing surgery in the neonatal period, a survival rate of 37%.

For comparison, a Buffalo survey for the period 1949–64, reported a survival rate of 31% (10 out of 32) in this age group (Lambert *et al.*, 1966). The figure from New Zealand for 1969–71 was 50% (6 out of 12) survival (Barratt-Boyes *et al.*, 1972).

Towards the latter part of the decade cardiac catheterisation was being widely used because of the improvement in mortality from heart disease at this age (Fyler, 1968, 1969; Varghese *et al.*, 1969). For example, the procedure of balloon atrial septostomy during cardiac catheterisation introduced in this period greatly accelerated the improvement in the survival rate of D-transposition of the great arteries. Surgical techniques suited to the smaller infant also became applicable (Mustard *et al.*, 1970; Edmunds *et al.*, 1972; Barratt-Boyes *et al.*, 1973).

The recognised need to improve case finding and facilitate treatment was first appreciated by the New England Regional Infant Cardiac Program in 1969 (Fyler *et al.*, 1972) and within 4 years the case study within that programme had been shown to be complete (Nadas *et al.*, 1973).

At the turn of the decade, the Study Group of Congenital Heart Disease of the Intersociety Commission for Heart Disease Resources was recommending a stratified system to promote optimal care for all ages (Engle, 1972).

With better understanding of the biological changes occurring in hypoxia and congestive heart failure in the newborn with serious heart disease, management of these changes pre- and postoperatively improved and aided in the survival of the patients (Rowe, 1970; Talner and Ithuralde, 1970; Gersony and Hayes, 1972; Talner and Campbell, 1972).

In an attempt to evaluate the impact of these changes, we have reported here our experience for 1975 and compared it with that for 1965. The number of referrals and patients with structural heart disease (226) seen in one year, was equal to the total seen in the 5 years before the 1960 report. A few changes were noted in the incidence of various malformations. The obvious increase in the incidence of PDA is related to the survival of increasingly more premature infants in whom the incidence of PDA is rising (Siassi *et al.*, 1976).

The sick cardiac patient in 1975 was referred and seen earlier than in 1965. Before cardiac catheterisation, a number of newer noninvasive assessments helped to plan invasive investigations and decreased the time and improved the quality. Such assessment included the use of blood–gases to determine the acid-base status, the hyperoxic test for cyanotic patients, and echocardiography (Rowe, 1970; Talner and Ithuralde, 1970; Godman *et al.*, 1974; Hagler, 1976; Meyer, 1977; Williams and Tucker, 1977). The interval from first assessment to cardiac catheterisation decreased with greater severity of cyanosis or congestive heart failure, reflecting the trend towards earlier and more complete investigations.

With the more aggressive and newer approach to investigation, the prognosis with treatment is improving. In 1965, 61% of neonates were surviving one month after medical treatment, but by 1975 the figure was 75% ($0 \cdot 02 < P < 0 \cdot 025$). A number of factors influence the result of medical treatment. If the patients with PDA are excluded, the survival rate with medical treatment was 58% in 1965 and 67% in 1975 ($\chi^2 = 1 \cdot 8$); the difference is not significant because of the smaller number of cases, particularly in 1975. Some patients will be treated medically because the lesion may be inoperable, as with aortic valve atresia, while others will have quite minor defects and transient disturbances which respond well to medical treatment.

With improved surgery and perioperative care, the survival rate in the first month after surgery rose from 37% in 1965 to 70% in 1975 ($P<0\cdot005$).

Supported in part by grants from the Ontario Heart Foundation.

Seroepidemiology of cytomegalovirus infections during the first years of life in urban communities

N. CABAU, M. D. LABADIE, C. VESIN, J. FEINGOLD, AND A. BOUÉ

Groupe de Recherches de Biologie Prénatale, INSERM U 73, Paris

SUMMARY Using indirect haemagglutination assay, combined with a collection of blood samples on blotting cards, seroepidemiological surveys of cytomegalovirus infections during early infancy have been done in different populations (French and immigrant) in urban areas. The comparison of CMV antibody status of mothers and their children at 10 months and at 2 years of age enables possible factors of viral transmission to be defined. During the first year of life, seropositive mothers were the only source of infection and they remained the main source during the second year. Socioeconomic class and educational level are determinant factors in the incidence of viral transmission.

There are wide variations in the incidence of infection by cytomegalovirus (CMV) in infants, related to socioeconomic classes and ethnic groups (Lang, 1975; Hanshaw, 1976). Epidemiological analysis of these variations is needed but this requires large surveys in different populations. This has been difficult because virus isolations cannot be used in large surveys, and serological tests have been made mainly by complement fixation (CF), a test having variable sensitivity; some CF-negative subjects had detectable CMV specific antibodies when more sensitive techniques (immunofluorescence, platelet-agglutination) were used (Weller, 1971; Stagno *et al.*, 1975).

The indirect haemagglutination (IHA) assay (Fucillo *et al.*, 1971; Huraux *et al.*, 1971) is a sensitive and specific technique for detecting CMV antibody and it can be used on a large scale for seroepidemiological surveys, especially when it is combined with the collection of blood samples on blotting cards requiring only a few drops of blood (Cabau *et al.*, 1976). We used this technique in a seroepidemiological study of CMV infections on infants during the first two years of life in different urban populations.

Subjects and methods

This study was carried out at two public health centres where children are seen for health check-ups at ages 10 months, 2 years, and 4 years. Children and their mothers spend between 3 and 4 hours in the centre during which time the child has a complete medical examination and some laboratory tests, and the mother has a psychological interview. The first centre (centre A) is in Clichy, a suburb north of Paris in which socioeconomic conditions are generally low and housing facilities poor. The second (centre B) is in the 13th district of Paris (south); a large part of it has recently been rebuilt with modern apartments, and it is inhabited mainly by the middle class. In both centres about 80% of people are French, the others are immigrants mainly from Africa, Spain, or Portugal. A blood sample was taken from the finger of mother and child, and sometimes from the father, filling the three circles of the blotting cards for a PKU test.

Information about the socioeconomic conditions of the families was obtained and clinical investigations were made by nurses and paediatricians not connected with the study. Once a week the cards were posted to the laboratory.

Serology. On arrival at the laboratory the cards were stored at 4°C. Serum was eluted from the dried blood specimens collected on the three circles in 1 ml buffer, giving a dilution of about 1:10 of the serum.

Serum was eluted within two weeks of taking the blood specimen. IHA assays were used for CMV antibody with the AD-169 strain of CMV as source of antigen, using the technique of Fucillo *et al.* (1971) modified by Cabau *et al.* (1976). Each sample was titrated from 1:10 up to 1:5120; mothers with an antibody titre < 1:10 and 10-month-old children with an antibody titre < 1:40 were considered negative. A previous longitudinal serological study had shown that in some infants born to CMV antibody-positive mothers, maternally-transmitted CMV antibodies could still be detected at 10 months by IHA assay, but the titres were < 1:40 (Cabau *et al.*, 1977). After a primary CMV infection proved by the presence of CMV antibody in IgM fractions, antibody titres were >1:40 at 10 months in every case; so in this study any infant with a CMV antibody titre >1:40 was presumed to be infected. It is not possible to establish if some of these infections were acquired *in utero.*

Results

CMV antibody studies in mothers and their 10-month-old children. 229 mothers and their children were tested at centre A and 399 at centre B (Table 1). At centre A, 71·6% of the mothers had CMV antibody compared with 56% at centre B. In the French mothers, 66·5% of them gave seropositive results at centre A compared with only 47·4% at centre B. At both centres a high percentage (about 90%) of immigrant mothers had CMV antibodies.

Comparison of CMV antibody in the 10-month-old infants shows striking differences: in centre A, 28·4% were seropositive; in centre B, 10%. Among French children 25·8% were seropositive in centre A, and 5·1% in centre B. A small difference was noted among immigrant children: 38% in centre A, 27% in centre B.

Table 1 *CMV antibody status of mothers and 10-month old children*

	Spanish–Portuguese	16	14 (87)	5 (35)
	Others	4	3	3
	Total	229	164 (71·6)	65 (28·4)
B	French	310 (77·7%)	147 (47·4)	16 (5·1)
	Immigrant			
	African	45	37 (82)	11 (24)
	Spanish–Portuguese	16	15 (94)	3 (19)
	Others	28	25 (89)	10 (35)
	Total	399	224 (56)	40 (10)

All 10-month-old infants who were seropositive had seropositive mothers, while none of the seronegative mothers had a seropositive child. Among seropositive mothers, in centre A 47 (39%) of 121 French mothers and 18 (42%) of 43 immigrant mothers had a seropositive child: in centre B 16 (11%) of 147 French mothers, and 24 (31%) of 77 immigrant mothers had a seropositive child. The serological titres of mothers were not related to the fact of whether or not their children were seropositive.

Some factors which may affect the transmission of virus from mother to infant were studied. There were no differences in the proportion of children delivered by caesarean section, nor were there differences in the proportion of children who attended day nurseries during the first months of life.

The proportion of children who were breast fed by seropositive mothers was studied in relation to the antibody status of the child at 10 months of age (Table 2). When results of the two centres were combined, significant differences (but only at the 5% level) were found between seropositive children (29% were breast fed < 8 weeks and 23% >8 weeks) and seronegative children (20% < 8 weeks and 15% >8 weeks).

At both centres certain socioeconomic factors (housing, education) were correlated with CMV antibody status of the mother and the child. In centre A there were no differences as all these people were in lower socioeconomic classes. In centre B some significant differences emerged: if both mother

Fathers with only elementary education	Total	27	12	13
	French	35	9	8·7

and child were seropositive their socioeconomic conditions tended to be low (Table 3).

The educational level of the fathers was compared. In French families, for which information was more reliable, in cases where both mother and child were seropositive, only 35% of fathers had had elementary education alone, compared with 9% of fathers in the other two groups.

Development of CMV antibodies in children at 10 months and 2 years and in their mothers. At centre B we collected blood samples from 262 mothers and their children at a second check-up examination at 2 years of age. Table 4 shows correlations between the results for each mother and child according to the antibody status of the 1st and 2nd samples. In 247 (94·3%), no change was observed in the CMV antibody status of mother and child. Nine CMV seronegative 10-month-old children with seropositive mothers became seropositive at 2 years of age. Two CMV negative 10-month-old children became seropositive but their mothers remained seronegative. Four seronegative mothers became seropositive and, in two instances, the child also became seropositive.

Differences were found between the French and immigrant families. In the 224 French families, 13 (6%) had a seropositive child at 10 months and 20 (9%) at 2 years. If the French seropositive mothers are considered, 13 (13%) out of 97 had a 10-month-old seropositive child and 18 (18%) out of 100 a seropositive child at 2 years. In the 38 immigrant families 12 (31%) had a seropositive child at 10 months and 18 (47%) at 2 years. In the group of seropositive mothers the figures are respectively 12 (34%) out of 35 and 18 (50%) out of 36.

Among factors which may indicate a possible source of CMV infection we noticed that in the 9 children who had seropositive mothers at 10 months and who became seropositive at 2 years, 6 stayed in day nurseries and 3 were nursed at home by their mothers. The 2 children who became seropositive with their mothers still seronegative, and the 2 children who seroconverted, as did their mothers, attended day nurseries from age 4–5 months. In the two observations in which the mothers became positive, only in the 2nd sample was the child nursed by the mother.

As a result of the clinical examination of the infants at 10 months and at 2 years, nothing of note was detected in those children with CMV antibodies.

Discussion

The use of IHA assays of blood samples collected on blotting cards is practical for surveys such as this. Samples may be posted, as an earlier study (Cabau *et al.*, 1976) showed that if elution is done within 2 weeks, correlation with titres using conventional serum samples is good. Even in specimens with low titres, no false-negatives were found. The method is useful for large surveys, and is accepted readily by the population (especially in infants from whom it is easy to obtain a few drops of blood) and by the doctors and nurses who collect the samples.

The presence of CMV antibodies in a mother at the time of the visit of her 10-month-old child probably reflects her antibody status at pregnancy. Of the 262 women who were tested twice at an interval of 14 months, only 4 showed seroconversion. Of the mothers who were seropositive in both tests, none showed significant change in titre. This stability of CMV antibody titre using IHA assay contrasts with fluctuations of CF antibody titre (Waner and Weller, 1973).

In this study the presence of CMV antibody after a primary infection in the child could clearly be seen to relate to the presence of CMV antibody in the mother, consistent with earlier reports (Levinsohn *et al.*, 1969; Andersen *et al.*, 1972; Leinikki *et al.*, 1972; Granström *et al.*, 1977).

Intrapartum contact with infected cervical secretions has been supposed to be the main cause of these

Table 4 *CMV antibody status of mothers (M) and their children (C) at 10 months and 2 years of age*

early infections. A longitudinal study on some children without specific IgM antibody at birth, but in whom CMV antibody was present at one year, showed that they had all acquired detectable specific IgM antibody between 3 and 6 months of age, suggesting early contamination, probably an intrapartum viral transmission (Cabau *et al.*, 1977). The fact that the incidence of caesarean sections did not vary in the different groups may be due to the fact that it was not possible to determine whether caesarean sections were before or after membrane rupture.

The percentage of children who were breast fed is significantly higher (but only at 5% level) in the group of children who had a primary CMV infection. When these results are correlated with socioeconomic criteria (e.g. parents with primary educational standard only) the difference remains. The high frequency of breast feeding is not related to low socioeconomic conditions, in agreement with general observations in French urban populations.

Consideration of the 13 children who showed CMV seroconversion between 10 months and 2 years supports the idea that mothers are the most important source of infection (9/13). Other sources may exist; for instance, both children who acquired CMV antibodies while their mothers remained negative attended nurseries. In the 2 cases where mothers and children both became CMV seropositive, the children also attended day nurseries and it is not known whether the mother or the child was first infected.

We conclude that during the first year of life mothers constitute the main, if not the only, source of CMV infection, and they remain the most common source of infection during the 2nd year of life also. In seropositive mothers CMV has been isolated in cervical secretions and in milk (Hayes *et al.*, 1972), and CMV infection is also considered a 'kissing disease'. During the 2nd year of life some extra-maternal sources of infection appear. Close contact between children in day nurseries is a possible mode of spread, but seems rare: 47% of seronegative children with seronegative mothers attended day nurseries, but no more than 4 children were infected by CMV.

This survey also demonstrates the importance of socioeconomic conditions in the transmission of CMV infections during the first 2 years of life. The incidence of infection depends on two factors: (1) the percentage of seropositive mothers, the potential source of virus, and (2) the percentage of infection of children from seropositive mothers.

In our groups of differing socioeconomic class, the percentage of seropositive mothers differed (centre A 66·5%; centre B 47·4%) as did the frequency of infection in their children (centre A 38·8%; centre B 10·8%). These two factors result in figures of 5 to 25% for the acquisition of seropositivity by 10 months in the two groups. In other surveys on French infants we have found a figure of 5% in a rural group and 76% in a poor urban group (Boué *et al.*, 1976, and unpublished).

In immigrant groups, the percentage of seropositive mothers was about 90%. They were infected mainly in their native country, but a slight difference is shown in the percentage of their seropositive children (centre A 41·8%; centre B 31·1%). In a previous study of very poor immigrant families living in Paris suburbs, 90% of the infants were seropositive (Boué *et al.*, 1976), a high frequency of early acquisition of antibody and similar to that observed in African populations (Lang, 1975; Cabau *et al.*, 1977). The improvement in living and educational standards of immigrant families reduces the frequency of early infection. It is of note that in centre A where the standard of living was similar in both French and immigrant groups, the percentages of seropositive children born from seropositive mothers were also very similar. In contrast with the above figures, only about 5% of 'middle-class' 10-month-old children have CMV antibodies.

These facts underline the importance of the standard of living in determining the transmission rates of CMV infections from mothers to infants. Not only are economic conditions (housing, income of the family) relevant, but so also are the prevailing hygiene habits, and these can be influenced by education.

We have found that the use of IHA assays of blood collected on blotting cards provides a practical tool for large surveys. What is needed is to follow-up pregnant women and their babies in different population groups, and then measure the incidence of intrauterine infections and their relation to living standards and personal hygiene. Such studies are indispensable if policies leading to prevention are to be formulated.

We thank pediatricians, biologists, and nurses from the Centres de Bilans de Santé de l'Enfant, Chantal Duros and Monique Coulon for technical assistance, Guillaume Arlet for collecting the data.

This work was supported by Institut National de la Santé et de la Recherche Médicale (Grant CRL 76.5.149.8).

The spread of Coxsackie B1 infection

T. W. HOSKINS, JOAN R. DAVIES, A. J. SMITH, KATHRYN COLLINGHAM,
AND ROMA N. CHAMBERLAIN

Christ's Hospital School, Horsham; Public Health Laboratory, Guildford; and Central Public Health Laboratory, London

SUMMARY During June and July 1977 5 junior boys in a boarding school for 800 pupils became ill with a mild infection caused by Coxsackie B1. The school had been taking part in a vaccine trial, and paired blood samples had been taken from new entrants in October 1976 and October 1977. 18% of the boys susceptible to the infection developed antibodies. The results suggest that dormitories are more important than the day-to-day contacts in the spread of infection. The advisability of nursing children with known or suspected enterovirus infections in open wards in hospital is questioned.

The interfamilial and institutional spread of Coxsackie B2 and B5 viruses has been well documented (Carmichael *et al.*, 1968; Broughton and Gostling, 1969; Lapinleimu and Kaski, 1972; Eilard *et al.*, 1974), but there have been few accounts of Coxsackie B1 (Yodfat and Nishmi, 1973). *Communicable Disease Reports* (Public Health Laboratory Service, 1964–1977) show that since 1967 there have been two small outbreaks in England and Wales, the first began in 1970 and the second in 1976 (Figure). Each lasted two years, the distribution of cases being biphasic, peaking in the summer months.

Christ's Hospital is a boarding school for 800 pupils aged between 11 and 19 years. The younger boys live in six houses. They are in forms for teaching, and then are split into sets for mathematics, French, Latin, etc., which are constituted differently from forms, and all the boys use a central dining hall. The range of contacts during the day must, therefore, be large. During June and July 1977, 5 junior boys became ill with a mild infection caused by Coxsackie B1. The school had been taking part in a trial of inactivated influenza vaccine (Hoskins *et al.*, 1976), and paired blood samples had been taken in October 1976 and October 1977 from 124 new entrants. This paper describes the spread of the infection.

Methods

Virus isolation. Throat swabs were collected into transport medium at the onset of illness. In the laboratory the specimens were inoculated into primary rhesus monkey kidney, human embryonic lung fibroblast, and Hela cell tissue cultures. These were incubated, rolled at 35°C for 15 days, and examined daily for cytopathic effect. Coxsackie B1 isolates were identified by neutralisation tests on the tissue culture fluids.

Neutralisation tests. Blood samples were collected in October 1976 and October 1977, the sera were stored at − 20°C until tested. Serum neutralisation tests were carried out in flat-bottomed microtitre trays using $0\cdot05$ cm^3 unit volumes. Serum dilutions were prepared in the trays and 1 unit volume of Coxsackie B1 virus was added to each serum dilution. After mixing, trays were left at room temperature for one hour, when 1 unit volume of a suspension of Vero cells was added to each well. Trays were incubated in a moist chamber for 3 days at 35°C. Presence of specific antibody was judged by inhibition of cytopathic effect. Sera with titres < one in 20 were recorded as 'without antibody'.

Results

Clinical findings. The 5 boys were aged between 12 and 13 years. All complained of headaches and

sore throats, and 4 of them had fevers of >38·3°C. In these boys the fever lasted from 2 to 5 days and the total length of illness was 6. In 2 boys there was some injection of the fauces and, in a 3rd, slight neck stiffness. The 5th boy was not pyrexial and spent only one day in the school infirmary. Convalescence was uncomplicated and there were no sequelae.

Epidemiology. During the period 13th June–11th July 1977, throat swabs were taken from 18 boys in the junior houses. Coxsackie B1 was isolated in 5. There were no viral isolates in the remaining 13. Throat swabs were also taken from 28 boys in the senior houses, none of which showed evidence of Coxsackie B1 infection. Thus, from these results and the clinical picture, the outbreak appears to have been confined to the junior houses. 124 new entrants in October 1976 had had sera taken. 24 (19%) had Coxsackie B1 antibodies and 100 (81%) were negative. By 1977, 18 of these were positive, suggesting that 18% of the boys known to have been susceptible to the infection had developed antibodies during the previous year. These included 2 with positive throat swabs.

Spread in the classrooms

The boys from the junior houses are in three form groups—II, III, and LE. Table 1 shows that the 5 boys with positive throat swabs were in forms IIB, IIIA, B, C, and E. The results of the neutralisation tests show that, of the 124 boys who had paired sera taken in the individual classes, there does not appear to be any association between the clinically

confirmed cases and those with serological evidence of a subclinical infection. In forms IIB, IIIA, and IIIC, both clinical and subclinical infection occurred. In forms IIIB and IIIE, both with clinical cases, there was no evidence of seroconversion among those who had paired sera taken, whereas in forms IIA, C, D, and E where there were no clinical cases, there was serological evidence of subclinical infection.

Spread in the dormitories

Table 2 shows that the 5 ill boys with positive swabs came from two houses—Leigh Hunt A and Barnes A. Each of the six junior houses has two dormitories with about 30 boys in each. The distance between any two beds is 900 mm in accordance with *The Standards for School Premises Regulations* (Great Britain Statutory Instruments, 1972). In Leigh Hunt A one of the boys with a positive throat swab slept in the upper dormitory and the two others in the lower dormitory. In Barnes A one was in the upper and one in the lower dormitory.

The proportion of boys who had paired sera taken was similar in each house.

In Leigh Hunt A, of the 7 boys who had seroconverted, 4 slept in the upper dormitory, 3 of them in adjacent beds. The beds of the 3 in the lower dormitory were not close together.

In Leigh Hunt B, all 4 boys with a subclinical infection came from the upper dormitory. One had been sleeping in the infirmary throughout June because of nocturnal epilepsy.

In Barnes A, the 3 boys who had seroconverted slept in widely separated beds in the upper dormitory. (Paired sera had not been taken from the clinical cases.)

In Barnes B, 4 boys had evidence of a subclinical infection. One slept at home and the remaining 3 boys were in the lower dormitory and slept in adjacent beds. There was no evidence of infection in the upper dormitory.

There were no known cases, clinically or subclinically, in the four dormitories of Maine A and B, although 83% of the boys in these houses had no detectable antibody to Coxsackie B1 in October 1976.

Thus, clinical and known subclinical infection was confined to 6 of the 12 dormitories. In two houses the infection occurred in only one dormitory. Of the 18 boys with paired sera who showed evidence of infection, two groups of 3 slept in adjacent beds.

Discussion

The Coxsackie B group of viruses are associated with a broad spectrum of clinical illness, ranging from a mild febrile infection to severe encephalitis (Kibrick, 1964; Assaad and Cockburn, 1972). A fatal case due to Coxsackie B1 in a newborn baby has been reported (Wright *et al.*, 1963).

This outbreak was not serious in itself. The results suggest that the dormitories and sleeping quarters are more important than the day-to-day contacts in the spread of this infection. While this has obvious implications in boarding schools and children's homes, it also raises the question of the advisability of nursing children with known or

Glycosylated haemoglobin levels in children with diabetes mellitus

M. L. WILLIAMS AND D. C. L. SAVAGE

Bristol Royal Hospital for Sick Children, Bristol

SUMMARY Total glycosylated haemoglobin (HbA_1) levels were measured in 94 diabetic children aged between 3 and 19 years. The results were compared with traditional methods of assessing blood glucose control. HbA_1 levels correlated with home urine glucose testing ($P<0 \cdot 05$), with 24-hour urine glucose excretion ($P<0 \cdot 01$), and with height velocity ($P<0 \cdot 001$). Within the first two of these parameters there was a wide scatter of results, suggesting the inaccuracy of these methods for assessing control. The association of raised HbA_1 levels with height velocities < 10th centile shows the effect of poor control on growth. HbA_1 may prove to be an objective method for assessing long-term blood glucose levels in diabetes, and thus it may be possible to determine the effect of good control in the prevention of the various diabetic complications.

The long-term complications of diabetes may have a multifactorial basis and it is still uncertain whether their development is related to blood glucose control. One of the reasons for the difficulty lies in our inability to assess accurately the degree of hyperglycaemia in individual patients. Recently it has been shown that an objective method of estimating control is the measurement of glycosylated haemoglobin (HbA_1) as this compound reflects the mean blood glucose concentration during the previous 2 or 3 months (Koenig *et al.*, 1976b; Gabbay *et al.*, 1977). We therefore examined the correlation between HbA_1 levels and those methods of assessment which are generally used in children with diabetes.

Patients and methods

All the children were attending the paediatric outpatient clinic regularly every 3 or 4 months. Their ages ranged between 3 and 19 years. They were being treated with Monocomponent insulins (Novo Laboratories), once-daily Monotard insulin in the younger children and twice-daily Actrapid and Semitard insulin in the older ones. Control value for HbA_1 levels were obtained in 14 nondiabetic children aged between 5 and 15 years. The controls were randomly selected from children attending the outpatient department; none had any specific disease.

Four methods of assessment were used: HbA_1 levels, twice-daily home urine testing, 24-hour urine glucose output, and height velocity. The home urine tests were those recorded during the previous 3 months before the level of HbA_1 had been examined. The urine tested was the 2nd specimen passed before breakfast and before the evening meal. The results were classified as good (50% or more tests with no glycosuria and <1 in 5 showing 2% glycosuria), fair (<50% tests negative and <1 in 5 showing 2% glycosuria), and poor (<25% tests negative or >1 in 5 tests showing 2% glycosuria). The 24-hour urine glucose output was measured in 82 children and expressed as a percentage of the planned carbohydrate intake. In the prepubertal children the height velocity during the previous year was expressed as a height velocity centile according to age.

Total glycosylated haemoglobins A_{1a}, A_{1b}, and A_{1c} (HbA_1) were measured in duplicate by column chromatography using the method of Welch and Boucher (1978). The results are expressed as a percentage contribution of HbA_1 to the total Hb concentration. The index of precision based on analysis of paired results was ± 0·63% (Whitby *et al.*, 1967).

Results

HbA_1 levels in the control group of children were between 7 and 10% (mean 8·9%). The levels in the

Bristol Royal Hospital for Sick Children
M. L. WILLIAMS, senior registrar
D. C. L. SAVAGE, consultant paediatrician

diabetic children ranged from 8 to 23% (mean 14·7%).

There was a significant difference between the mean HbA_1 levels of those assessed as having good control with home urine tests (mean 13·2%) and those assessed as being poorly controlled (mean 16·4%) ($P<0·05$). There is however a wide scatter in all columns (Fig. 1). Nine of the 13 children assessed as well controlled but with HbA_1 levels above the mean were on once-daily insulin (Monotard), and in 7 of these 9 children the 24-hour urine glucose loss was between 20 and 70% of the planned carbohydrate intake (mean 44%).

A correlation ($r = 0·46$, $P<0·01$) was found between HbA_1 levels and the 24-hour urine glucose output expressed as a percentage of the planned daily carbohydrate intake (Fig. 2).

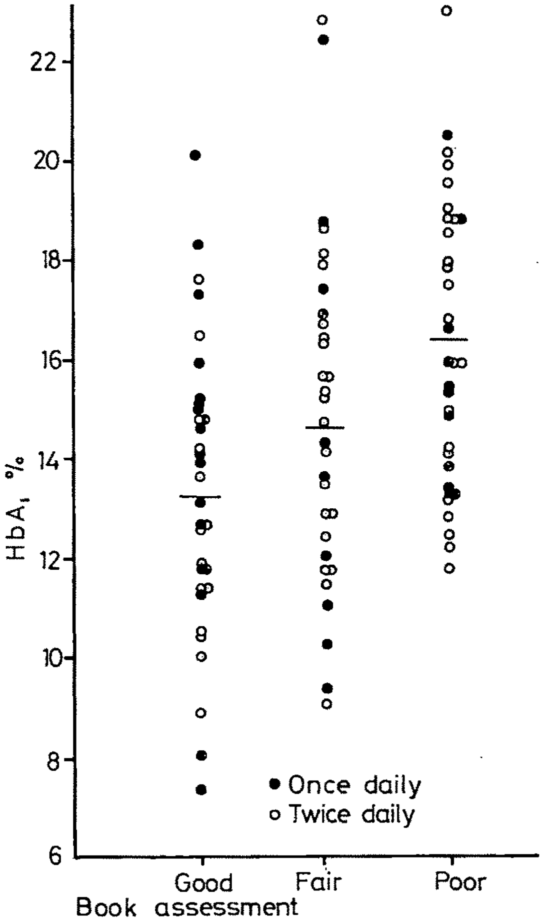

Fig. 1 *Levels of HbA_1 compared with assessment of control by twice-daily home urine tests.*

In those children with height velocity <10th centile, the mean HbA_1 level was 16·2% compared with 12·4% in those with height velocities >10th centile ($P<0·001$) (Fig. 3).

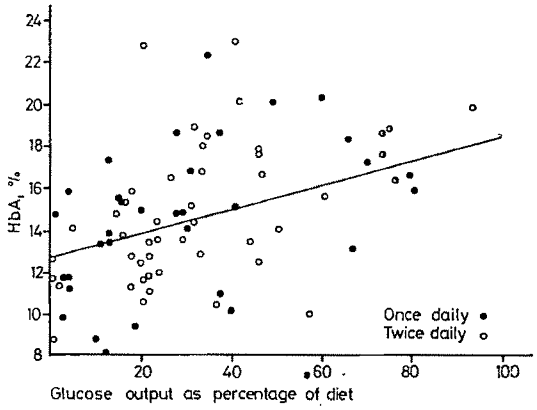

Fig. 2 *Correlation of HbA_1 with 24-hour urine glucose output expressed as percentage of planned carbohydrate intake.*

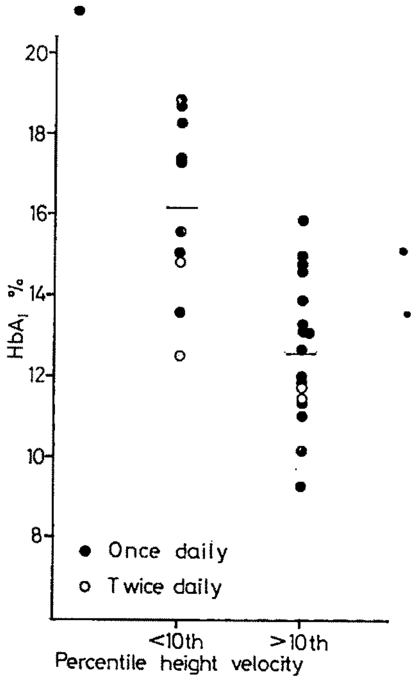

Fig. 3 *Levels of HbA_1 in prepubertal children whose height velocity was less than or greater than the 10th centile.*

Discussion

The glycosylated haemoglobins (A_{1a}, A_{1b}, A_{1c}) are structurally indentical with HbA except for the presence of a glucose group linked to the terminal amino-acid of the β-chain. Glycosylation of HbA occurs by a slow nonenzymatic process in the circulating erythrocyte and forms a stable and relatively irreversible ketamine linkage (Bunn *et al.*, 1976). This results in the continuous formation and accumulation of glycosylated haemoglobins within the erythrocyte during the 120-day life span, and therefore reflects the degree of hyperglycaemia during this period. In health the glycosylated haemoglobins make up less than 10% of the total HbA. Of the 3 glycosylated haemoglobins, HbA$_{1c}$ makes up the greatest fraction and appears to correspond most closely to the degree of hyperglycaemia (Koenig *et al.*, 1976b).

Several investigators have examined the relationship of HbA$_1$ with the more commonly used methods for assessing control in diabetes. They found a correlation of HbA$_1$ levels with physician's rating, urine testing, 24-hour urine glucose estimations, fasting plasma glucose levels, serum triglyceride levels, and response to treatment after diagnosis (Koenig *et al.*, 1976a; Gabbay *et al.*, 1977; Gonen *et al.*, 1977; Lanoe *et al.*, 1977; Peterson *et al.*, 1977; Koenig *et al.*, 1976b; Ditzel and Kjaergaard, 1978). However in nearly all these studies the scatter of results was wide, showing that present methods are inadequate for assessing control in diabetes. Indeed in some studies there was no correlation between the HbA$_1$ level and certain of the parameters used in assessment (Gonen *et al.*, 1977; Lanoe *et al.*, 1977). Overall, however, the evidence suggests that the measurement of HbA$_1$ may be the best method yet available for measuring blood glucose control (Koenig *et al.*, 1976a).

Although we found a correlation of HbA$_1$ levels with our present methods of assessing diabetic control, there is within each parameter a wide scatter of HbA$_1$ levels. This is not surprising as home urine tests are not an accurate method of assessment (Malone *et al.*, 1976), and the measurement of an occasional 24-hour urine glucose output cannot be regarded as an index of day-to-day diabetic control. In a review of studies evaluating the relationship of diabetic control with complications, Knowles (1964) concluded 'the most doubtful measurement of all is that of control'.

An objective parameter in assessing long-term control in children is height velocity. This study shows a clear difference in HbA$_1$ levels between those children who have grown poorly and those with satisfactory growth. Others have not found any correlation between height velocity and traditional methods of assessing control (Jivani and Rayner, 1973; Craig, 1977) which may reflect the inadequacy of these methods, and suggests that HbA is a more accurate method of assessment.

Like others we found that a number of patients thought to be well controlled had raised HbA$_1$ levels. This was particularly apparent in a group of children who appeared well controlled as assessed by home urine tests. In some of these children inaccurate urine testing and book-keeping may account for the discrepancy. However, the majority were young children (<8 years) whose urine tests were generally both checked and recorded by the parents. These children were all on once-daily long-acting insulin injections. This type of insulin controls blood glucose levels between meals but does not prevent the postprandial blood glucose surge (Gokal *et al.*, 1977). Hence, urine tests before meals show little or no glycosuria but miss the marked hyperglycaemia which occurs after each meal. This was reflected in the children's high 24-hour urine glucose output and raised HbA$_1$ levels. It is now our policy to combine a quick-acting soluble insulin (Actrapid) with the once daily long-acting insulin (Monotard) to reduce the postbreakfast hyperglycaemia.

Our data confirm that the measurement of glycosylated haemoglobin may have an important role in evaluating diabetic control. They indicate the limitations of present methods of assessment and show how improbable it is that with these conventional methods we can hope to show a correlation between diabetic control and complications. Prospective longitudinal studies of HbA$_1$ in diabetes may not only provide an objective measurement of overall blood glucose control, but it may also more accurately relate this to the development of the long-term complications of diabetes.

We thank Dr Charles Pennock for advice, Angela Brimble and Caroline Owens for technical assistance, Dr A. Morris and Mr B. Harcourt for statistical help, Novo Laboratories for financial support, and Sue Osborne for typing.

Drug metabolism in malnourished children: a study with antipyrine

M. HOMEIDA, Z. A. KARRAR, AND C. J. C. ROBERTS

Department of Medicine, Bristol Royal Infirmary, and Department of Paediatrics, University of Khartoum

SUMMARY The effect of malnutrition on hepatic drug-metabolising enzymes was investigated in 8 Sudanese children aged between 9 and 12·5 years using as a model the drug antipyrine. Antipyrine half-life and clearance were measured in the malnourished state and after 3 or 4 weeks of good nutrition. Associated with the improvement in nutritional state was a shortening of antipyrine half-life and an increase in its clearance. There was also a rise in serum triiodothyronine. It is concluded that poor nutrition is associated with impairment of drug metabolic capacity and that many factors are responsible.

Primary malnutrition is the most common medical problem in children in underdeveloped countries (National Institute of Child Health and Human Development, 1971) and is often associated with diseases requiring treatment with drugs. Deficiencies of essential nutrients have been shown to affect the activity of hepatic enzyme systems responsible for drug metabolism. In animal studies dietary withdrawals of protein, vitamin A, thiamine, riboflavin, vitamin C, and minerals have been found to decrease the activity of the mixed function oxidase system of enzymes in the liver and thus to depress the metabolism of certain drugs (Dixon *et al.*, 1960; Kato, 1967; Campbell and Hayes, 1974). Studies in humans deprived of at least one essential nutrient for variable periods have also demonstrated prolonged plasma disappearance of drugs (Conney *et al.*, 1977). In developing countries malnutrition comprises a chronic deficiency of macronutrients and micronutrients, and it is commonly associated with hormone deficiencies (Chopra and Smith, 1975) which in turn can influence hepatic drug metabolism. Alteration in body composition, particularly the presence of nutritional oedema, can also influence plasma disappearance of drugs by changing their volume of distribution.

This study was designed to investigate the effect of established protein-calorie malnutrition on drug metabolism in children and the effect of its treatment. The possible contribution of change in thyroid function to alteration in drug metabolism in malnutrition was also investigated.

Antipyrine was chosen for the study as it is rapidly and completely absorbed after oral administration, is extensively hydroxylated in the liver, is only 10% bound to plasma proteins, and is distributed in body water (Brodie and Axelrod, 1950). Plasma kinetics of antipyrine have been used widely as an indicator of hepatic drug metabolism (Stevenson, 1977).

Patients and methods

Eight children aged between 9 and 12·5 years were studied. In each child protein-calorie malnutrition was established at the beginning of the study. Selection of patients was based on the presence of all the following criteria: history of dietary inadequacy, weight <75% of the standard using the Wellcome Trust classification (*Lancet*, 1970); Hb <10 g/dl, serum albumin <35 g/l (3·5 g/100 ml) in the absence of other causes of anaemia or hypoproteinaemia; presence of signs suggesting vitamin deficiency—for example, angular stomatitis or dry flaky skin. No patient had peripheral oedema or ascites. In 6 patients investigations showed no concurrent disease and there was no recent drug administration. One patient had had malaria which had been treated before the start of the study, and one patient was found to have typhoid fever which was treated with chloramphenicol in the latter part of the study.

Patients were studied on admission to hospital and again after 3 or 4 weeks on a high-protein, high-calorie diet. The diet contained 5 g protein/kg in the form of meat, fish, and eggs, and adequate amounts of carbohydrates, vegetables, and fresh fruits. Vitamin supplement of the B-group was added with iron in the form of ferrous sulphate.

The following measurements were made: Hb, serum albumin, bilirubin, alkaline phosphatase, aspartate aminotransferase, serum thyroxine (T4), free thyroxine index (FTI), and triiodothyronine (T3). Plasma antipyrine kinetics were performed before and after treatment using the following procedure: after an overnight fast and withdrawal of blood for blank plasma, 600 mg antipyrine as a freshly prepared solution was given orally. Venous samples were drawn at 3, 6, 9, and 24 hours after the dose. Plasma was separated and stored at −20°C for future analysis. Plasma was sent frozen to Bristol for the assay of antipyrine levels using the method of Brodie *et al.* (1949).

Antipyrine plasma half-life ($t\frac{1}{2}$) was calculated from linear regression analysis of the log plasma concentration-time profile. Volume of distribution (Vd) of antipyrine was calculated as dose/plasma concentration antipyrine, extrapolated back to the time of administration. Clearance of antipyrine was calculated as $Vd \times 693 \div t\frac{1}{2}$.

Statistical analysis was carried out using Student's paired *t* test.

Results

The clinical condition of each patient improved during the study period. There were significant increases in weight, Hb, and serum albumin, although mean Hb and mean serum albumin did not reach normal levels (Table 1).

The mean baseline plasma T4 and FTI were normal and the change in these parameters after treatment was not significant (Table 1). However, T3 levels were low at the beginning of the study and rose to normal after treatment.

There were no abnormalities or changes in the levels of alkaline phosphate, bilirubin, or aspartate aminotransferase.

Antipyrine plasma kinetics are shown in Table 2. The mean volume of distribution of antipyrine was higher after treatment, but the difference was not significant and disappeared when corrected for change in body weight. There was a significant 33% shortening of antipyrine plasma half-life, and a significant 64% increase in plasma clearance after treatment for malnutrition.

Discussion

This study showed that drug metabolism is impaired in malnourished children and that impairment can be reversed within a month of starting an improved diet. Such a finding has not been previously reported.

The main observation is the shortening of antipyrine half-life and the increase in its clearance which occurred between measurements in the malnourished and treated states. In most patients the only treatment was dietary replacement. Two patients were receiving treatment for malaria and typhoid which might have influenced antipyrine kinetics. However, if these patients are excluded the change in antipyrine half-life is still significant. It is reasonable to conclude that the change in antipyrine kinetics

during the study period was related to altered nutritional state and that the results obtained at the beginning of the study reflected abnormally depressed drug metabolism due to nutritional deficiency. Evidence of an improvement in nutritional state is provided by the changes in bodyweight, Hb, and serum albumin levels.

The results of this study differ from those of Krishnaswamy and Naidu (1977) who compared groups of normal and malnourished adults. In their study the antipyrine half-life was normal in undernourished patients and was prolonged only in patients with nutritional oedema, possibly due to altered volume of distribution. However, exposure to environmental enzyme-inducing factors could not be excluded. In the present study the within-patient comparison excludes all such environmental factors. Furthermore the absence of change in volume of distribution, and the pronounced increase in plasma clearance of antipyrine with nutritional replacement, support the concept that malnutrition decreases the drug-metabolising capacity of the liver.

It is not possible to say which factor in the malnourished children was most responsible for the decreased drug metabolism, and it is likely that they were deficient of many of the essential nutrients which have been shown to affect hepatic enzyme systems. The reduced serum albumin provides evidence of protein malnutrition which may cause a reduction in total amount of microsomal enzymes. In the rhesus monkey, protein deprivation resulted in loss of liver weight with an associated decrease in concentration and activity of microsomal enzymes (Rumack *et al.*, 1973), and in rats protein deficiency induced fatty infiltration of the liver with reductions in the number of functioning cells and in total microsomal protein content (Campbell, 1977). Protein deficiency has also been shown to decrease *in vitro* microsomal oxidation of strychnine, aminopyrine, and ethyl morphine, and to reduce cytochrome P450 content (Campbell and Hayes, 1974).

The children in the present study received supplements of vitamin B, vitamin C-rich fruits, and oral iron. Drug-metabolising enzyme systems have been shown to be highly dependent on vitamin C status in animals (Campbell and Hayes, 1974). Supplementation of the diet of normal individuals with vitamin C has resulted in a substantial increase in antipyrine clearance (Houston, 1977), and vitamin C deficiency is partly responsible for the retardation of drug clearance in elderly people (Smithard and Langman, 1977), and in patients with liver disease (Beattie and Sherlock, 1976). It is possible that the vitamin supplements in this study accounted for some of the observed improvement in antipyrine clearance. As there is evidence that iron deficiency enhances drug metabolism (Langman and Smithard, 1977), the iron supplements are unlikely to have contributed to the change.

The findings of low T3 levels in the face of normal T4 and FTI in the malnourished children is in agreement with the results of other workers (Pimstone *et al.*, 1973; Chopra and Smith, 1975). It has been suggested that the low serum T3 level is due to a reversible defect in the extra-thyroidal conversion of T4 to T3 (Chopra and Smith, 1975). Similar results have been observed in patients with anorexia nervosa when the biotransformation of labelled testosterone and oestradiol was impaired in all patients studied. Drug metabolism was restored to normality by the administration of T3 and by reversion of thyroid function tests to normal after good nutrition (Fishman *et al.*, 1977). It is possible therefore that the low T3 levels in the present study could be a factor in the prolongation of antipyrine half-life.

The present study has shown a reduction in the metabolism of antipyrine in malnourished children which is reversible by proper nutrition. Many factors may have contributed to this finding. Dose requirements of drugs metabolised by microsomal hydroxylation in the liver in children are dependent on nutritional status.

We thank Miss J. Ford for excellent technical help.

Personal practice

Mourning by the family after a stillbirth or neonatal death

EMANUEL LEWIS

Department of Child and Family Psychiatry, Charing Cross Hospital

SUMMARY Failure of the parents to mourn after the sorrow of a stillbirth or neonatal death can result in dire consequences for the well-being of the family. Doctors and nurses should learn how to facilitate mourning and should accept the strange and sometimes bizarre forms this may take. When mourning is facilitated, the family is likely to adjust better to its bereavement.

Stillbirth is a common tragedy occurring in about one in 100 deliveries. Yet after a stillbirth everyone tends to behave as if it had not happened. In hospital bereaved women are usually isolated and avoided and then discharged as soon as possible. Although this is meant kindly, to protect the mothers from the painful awareness of live babies, it also means that the hospital staff do not have to face their own anxiety about stillbirth. Back at home, the family, friends, and professionals continue to avoid talking to the bereaved mother, depriving her of the talk that would help her mourn. There is silence. Statistical evidence shows that family doctors are astonishingly reluctant to know or remember anything about the patient who has a stillbirth (Bourne, 1968). This avoidance by the helping professionals extends into neglect of the study of the effect of stillbirth on the mother and the family. There is a conspiracy of silence. We seem unwilling to come to terms with the fact that it is a tragedy which can seriously affect the mental health of a bereaved mother and her family. After the failure to mourn a stillbirth, mothers can have psychotic breakdowns or there can be severe marital difficulties. Children born before or after a stillbirth where there has been a failure to mourn the stillbirth, can have severe emotional difficulties. Many mothers have mothering difficulties with the child born subsequently (Lewis and Page, 1978). The surviving twin of a stillbirth faces profound difficulties in life.

The psychoanalytical view of mourning is of an ongoing process during which the conscious and unconscious mind works on coming to an understanding of the memories, thoughts, and feelings about the dead person. The dead person is unconsciously imagined as being taken inside our mind and our body. The dead can be felt as dead inside us. We identify with the dead person. Doctors meet this phenomenon when a bereaved person develops imaginary symptoms related to the illness of the dead person. During the work of mourning we digest our memories and feelings about the dead and free ourselves from the identification. With incomplete or failed mourning the identification can persist and result, for instance, in a depressive illness with somatic symptoms. Or a failure to come to terms with our inevitably mixed feelings for the dead can lead to a denial of negative feelings and an overemphasis of positive feelings. A potentially dangerous idealisation of the dead person can result. When a mother idealises her dead child there can be dire consequences for the mothering of her subsequent children.

It is the nature of stillbirth that leads us all to avoid the subject. Bourne (1968) described stillbirth as a nonevent in which there is guilt and shame with no tangible person to mourn. A stillborn is someone who did not exist, a nonperson, often with no name. It is an empty tragedy and a painful emptiness is difficult to talk about. After a stillbirth there is a double sense of loss for the bereaved mother who now has a void where there was so evidently a fullness. Even with a live birth the mother feels a sense of loss but the consolation of a surviving 'outside baby' helps the mother to overcome her puzzling and

---

Charing Cross Hospital, London
EMANUEL LEWIS, consultant psychiatrist

bewildering sadness at losing her 'inside baby' (Lewis, 1976a). With a stillbirth, the mother has to cope with an outer as well as an inner void. There is an even more puzzling sense of nothingness for a mother who is anaesthetised at delivery—for example with a caesarean section.

Memory facilitates the normal mourning processes essential for recovery. With other bereavements there is much to remember. These memories can be shared and cried over with family and friends. Not so with stillbirth—there is no one to talk about and no one to talk to about it. The bereaved mother may herself avoid contact with people because of unconscious feelings of shame and guilt. Her shame is associated with the sense of having failed as a woman. She may feel that there is something wrong with her womb. Her guilt has to do with fantasies that her thoughts or actions have caused the death—for example, by having considered a termination of pregnancy or by having sexual intercourse late in pregnancy. If we allow mothers to isolate themselves we may seem to be confirming that their shame and guilt are justified. Many bereaved mothers keep their distress to themselves, not only to avoid too intense an awareness of their loss, but to protect others from distress. By so protecting others they deprive themselves of the talk which would aid mourning. And of course husbands and children also have their guilt about a stillbirth because of their mixed feelings about the pregnancy. This impedes their mourning.

To facilitate mourning I recommend that a stillbirth be managed by making the most of what is available and can be remembered. The aim is to fill the emptiness that impedes mourning (Lewis, 1976b). Bereaved parents should be encouraged to help lay out their dead baby. A post-mortem photograph, examination, and *x*-ray will assist genetic counselling. Parents should also be persuaded to take an active part in the certification of stillbirth, to name the baby, and to make the funeral memorable. The practice of burial in a common and nameless grave should be avoided. The family should be encouraged to attend the funeral or cremation and to know of a marked place or grave. Other children in the family find the idea of a stillbirth incomprehensible and frightening. Yet it is they, in particular, who tend to be left in the dark about the stillbirth, left without help with their grief.

It is my impression that if a stillbirth has been a real experience for the family in the ways that I have described, mourning will have been facilitated. This leads to fewer psychological problems for the mother and her family. When a stillbirth is managed in the way that I have suggested I believe that it is a helpful experience for staff and patients. However there is a need to be prepared for some upsetting and crazy experiences. The management of stillbirth causes considerable anxiety, particularly if the child is macerated as a result of intrauterine death or is malformed (Lewis, 1978). For this reason it is helpful if those managing such a painful happening as a stillbirth can have discussions with staff who have had experience of it. The reaction of parents and staff themselves to stillbirth and neonatal death can be disconcerting. The normal reactions to bereavement *are* disconcerting. Freud (1957) said of normal mourning that it would seem like an illness were we not aware of the bereavement. Most people know little of the natural history of the normal reactions of parents handling their dead babies.

With stillbirth or neonatal death, it is partly the loss of what might have been, the loss of experience in the future, which makes them such heart-rending and deeply frustrating experiences.

A baby of 27 weeks' gestation was resuscitated several times in the 10 days it survived. The mother had seen the baby collapse and thought it dead, but it was resuscitated to live a short time. With difficulty, the ward sister was able to arrange a funeral and cremation for this baby, even though it was under 28 weeks' gestation. The baby was laid out in the incubator. The mother was encouraged first to touch and then to hold him. She became frenzied, clutching her baby, and then stripping the clothes off. She kissed his navel and his penis. She forcibly opened his mouth and said, 'That's where his teeth would have been'. Then she 'walked' her baby on the floor. Soon the mother calmed down and gave the baby back to the sister. The sister was distressed but when later the parents came to see her, her impression was that this mother was coping better than many bereaved mothers.

The detailed study of the natural history of bereavement has shown that many seemingly crazy ideas and actions are within the normal range of responses to loss (Parkes, 1972). Although this mother's behaviour appears mad, if we examine it more closely we can see the sense in her behaviour. She was attempting to come to terms with the baby's lost future. In her mind she maintained the continuity of the cycle of life. By kissing the umbilicus she was remembering her creative link with the baby *in utero*; kissing the mouth may be linked to the kiss of life, to the resuscitation. The mother longed for her son to grow teeth and learn to walk, and kissing his penis could be considered a wish to restore her dead son's potential capacity to create life. Creating memories about her baby in this way facilitated mourning.

A nurse, a senior sister, suggested that the parents of a dying, severely brain-damaged 'prem' look at and touch their baby. Knowing that the mother had wanted to breast feed her baby, the nurse suggested that the mother might take off her blouse and hold her baby close to her skin. This suggestion by the nurse seems to ignore the critical state of the infant, and may have been provoked by her wish that this virtually dead baby might live. To the nurse's consternation the mother put the dying 'prem' to her breast, expressed milk into the infant's mouth, and then moved its mouth to encourage swallowing. When the baby died the parents washed and dressed him in the baby clothes that the nurse had suggested they bring with them. In her next pregnancy this mother's memory of her dead baby was of cradling him in her arms. So far, although at times tearful when remembering her dead child, she is making a good job of the mothering of her new baby. While the nurse went further than I would have advised out of my concern for the physical management of the admittedly moribund baby, nevertheless she may have helped the mother when the baby was beyond medical help.

A 28-week premature baby died at 3 days. The mother telephoned the nurse who suggested that the parents come to see their dead baby son. The mother asked if she could bring baby clothes and the nurse agreed. The nurse took the parents to the viewing room by the mortuary. They dressed their baby and told the nurse the baby's name. After this sort of experience with their dead baby many parents, because they find it helpful, keep in touch with the staff. The mother later visited the unit and asked the nurse whether she considered blue a morbid colour to paint their living room. She also said that she was learning to crochet. It seems to me that this mother was thinking about the blues, and perhaps associating blue with boys, and her dead son. She may also have been asking permission to go on living, to improve her living room, which unconsciously was probably symbolic of her womb, just as learning to crochet may have been symbolic of her making a new baby. She seemed to be asking the nurse if she could be considered the sort of woman who could be trusted with another baby. Unconscious destructive feelings to a lesser or greater extent are always present as part of the normal mixed feelings that a mother has about her pregnancies. After the baby died this mother feared that her unconscious destructive feelings were a reason for the child's death. Because of this she seemed to need the nurse's reassurance about her baby-making ability versus her destructiveness.

I am loath for parents to rush into pregnancy after a stillbirth until they feel that they have adequately mourned their dead baby. They need time to think through and come to terms with the stillbirth, and to understand how to avoid the idealisation of a dead baby that so often bedevils the life of subsequent children.

A premature baby died. The father gave away the baby clothes etc. The mother went home, took out a small bundle of baby clothes that she had hidden away, guessing that her husband might give the baby things away, and cried over the clothes.

The wife of a medical student studying anatomy had a stillbirth. He remarked to a fellow student that he wanted to get hold of his stillbirth to dissect it. His colleague was amazed, but now understands the father's need to have some tangible experience of his stillborn child, so as to facilitate mourning. This story seems upsetting but is an example of how bereaved parents will seek of themselves to get an experience of their stillborn, sensing that this will help them to mourn. Obviously this father would have benefited from other help.

Similarly many mothers seem to know that it would be helpful to look at their dead baby, although they are usually put off when they ask hospital staff whether they should do so. One mother in trying to get an experience of her stillborn child made the most of what she had seen—a cot and a wisp of black hair on the top of his head. This is now a dear memory for her.

A photograph of a dead baby can help parents who have been unable to see their stillborn child. Or other eyes that have seen can tell the parents. A husband carefully described to his wife how his stillborn daughter had looked, described her face and hair, her delicate normal body and limbs, and also the dark-stained blotches on one side.

A woman house surgeon did something like this for the parents of an anencephalic baby which her consultant had refused to allow her to show the parents. She described to the mother and father the normal body, the normal delicate hands and fingers, legs, feet, and toes of the anencephalic baby. The doctor also encouraged the father who had wanted to protect his wife by leaving her out of the funeral, to take her along. The doctor said it was also the mother's baby and so the father did take his wife to the funeral.

It is necessary to make recommendations about the management of stillbirth in hospital. I believe that parents left to themselves, and this is particularly so with domiciliary delivery, would do things better. You may feel that my suggestions about the management of stillbirth and neonatal death are silly. But I suggest that the normal 'rugby pass' management of stillbirth in hospital is rather more bizarre. I refer to the catching of a stillbirth after delivery, the quick accurate back-pass through the labour room door to someone who catches the baby and rapidly covers it and hides it from the parents and everyone. Our hospital culture tends to impede the normal healing process of mourning. We do this even by asking the mother whether she wishes to see her dead baby. Really what could be more natural? It heartens me when I hear of a father describing the baby in detail to his wife, of the mother who hid the baby clothes to cry over, or of the father who wished to dissect his baby, or of the mother who kissed and walked her dead baby. Sometimes people know how to help themselves. It is difficult in hospital. A senior midwife was encouraged by the obstetrician to show a stillbirth to the parents. She took the macerated stillbirth out of the labour room saying, with the irony of the unconscious, that 'to show them the baby would put them off stillbirth for life'. Fortunately this midwife recovered, brought the baby back to the parents and, with great sensitivity, showed them the normal limbs, fingers, and toes, and asked them the name of the baby.

In the Far East there is a cactus with white fragrant flowers that blooms briefly only every few years. Each bud opens and dies visibly in front of one's eyes within a few hours. A family may sit together and watch the birth and death of the flower, for it brings good luck. A Far Eastern couple buried their stillborn in a little grave with a small headstone inscribed with the name of this cactus given to their child. An act of creative poetic self-healing.

Short reports

Improved accuracy of continuous measurement of arterial oxygen tension in sick newborn infants

Criteria for reading and recalibrating the electrode

A. R. WILKINSON, R. H. PHIBBS, AND G. A. GREGORY

Departments of Pediatrics, Anesthesia, and the Cardiovascular Research Institute, University of California, San Francisco, USA

SUMMARY Improved accuracy of continuous arterial oxygen tension (Pao_2) measurement is obtained if allowance is made for the response time of the electrode. Recalibration is necessary only when Pao_2 measured in a blood sample differs from the electrode value by more than ±11·5 mmHg (1·5 kPa).

During the last 6 years continuously-recording intravascular oxygen electrodes have been developed (Parker *et al.*, 1971; Harris and Nugent, 1973; Goddard *et al.*, 1974). These instruments have shown that the arterial oxygen tension (Pao_2) in sick newborn babies may fluctuate widely, and that analysis of intermittent blood samples is often a poor reflection of the changes taking place. The ideal continuously-recording oxygen electrode would be accurate and reliable, and would not introduce any hazards that do not already exist with an umbilical arterial catheter (Kollmeyer and Tsang, 1974). Accuracy depends on the initial calibration against blood analysis of Pao_2, while reliability depends on knowing when to recalibrate.

Of the various electrodes that have been developed only one is commercially available.* We have devised a technique that greatly improves the accuracy of this instrument and we also report our criteria for recalibrating the electrode.

The instrument

The electrode is attached to the end of a 5 French gauge (1·67 mm) dual-lumen polyvinylchloride catheter. One lumen has a side hole and is used for blood sampling, fluid infusion, and pressure measurement. The other lumen contains the leads from the polarographic oxygen electrode which are connected to a battery-powered amplifier. A meter displays the reading of Pao_2. An optically-coupled recording unit enables a continous chart record of Pao_2 to be made. The output current of each electrode is tested before the catheter is individually packed and sterilised.

After the catheter has been inserted there is a gradual change in sensitivity of the electrode caused by membrane thickening as water is absorbed, and it is recommended that the electrode be calibrated after 15–30 min. The meter is read and a sample of blood is withdrawn for Pao_2 measurement. When the result is known the meter reading is adjusted by the ratio of the blood Pao_2 to the meter Pao_2. The accuracy of this method of calibration depends on the response time of the system and on any change in Pao_2 just before, or during, blood sampling. The electrodes used in this study had a 95% response time of between 40 and 60 seconds.

Patients

We placed 28 catheters in 24 newborn infants (birthweights between 0·6 and 3·6 kg, mean 2·15); each required an indwelling arterial catheter for clinical management. Most infants were born prematurely, with a mean gestational age of 34 weeks (range 24–44). 15 had birth asphyxia, 5 developed severe hyaline membrane disease, and 5 severe haemolytic disease; 4 had meconium aspiration, 2 polycythaemia, and one each, diaphragmatic hernia, delayed resorption of lung fluid, and viral pneumonia. Three infants died in the neonatal period.

We obtained consent from the parents to use this type of catheter instead of the standard polyvinylchloride umbilical arterial catheter†; often this was obtained some days before birth if there was premature labour or if elective caesarean section was planned.

*G. D. Searle & Co. Ltd., High Wycombe, Bucks.

Methods

We have already described our technique for catheterisation of umbilical arteries (Kitterman *et al.*, 1970). No alteration in our routine procedure was made and during this initial evaluation we did not rely on the continuous reading of Pao_2 for clinical management, but continued to sample blood at least every 4 hours for measurements of Pao_2, $Paco_2$, and pH (Radiometer PHM72).

The electrode was calibrated as soon after insertion as possible and a continuous record of Pao_2 made on a polygraph recorder (Grass model 7A). From this record it was apparent that Pao_2 was fluctuating, often by as much as 20 mmHg (2·7 kPa), even when the baby was sleeping and breathing quietly. In these circumstances if blood is sampled for analysis of Pao_2, the meter will read the correct value only after the response time of the electrode has elapsed. The meter reading at the time blood is being sampled will not reflect actual Pao_2 and this discrepancy may lead to unnecessary recalibration. During this study we read the meter at the time blood was sampled and then we allowed for the response time of the electrode and read it again 45 seconds after blood sampling. The Radiometer electrode value for Pao_2 was compared with the meter readings and the differences calculated. When the difference, even after allowing for the response time, was greater than 10 mmHg (1·34 kPa) we repeated the blood sample. In most cases the discrepancy between the meter reading and the Pao_2 in this second sample was <10 mmHg but if it again exceeded 10 mmHg we recalibrated the electrode. This decision was based on our feeling that when a discrepancy of >10 mmHg exists between the predicted value (catheter electrode) and actual value (Radiometer) of Pao_2, then the usefulness of the electrode for regulating oxygen and artificial ventilation, and for safely reducing the frequency of blood sampling is seriously diminished.

Results

Four of the 28 electrodes did not activate. The mean time to initial calibration of the remaining 24 electrodes was 74 minutes (range 18–240). Delay was in most cases due to a very unstable Pao_2 immediately after birth and during resuscitation.

The catheters were in place for between 2 and 135 hours (mean 43). During this time haematocrit varied between 18 and 72%, $Paco_2$ between 15 and 88 mmHg (2–11·7 kPa), and pH between 7·06 and 7·57. The Pao_2 meter was read at the time of blood sampling and 45 seconds later on 408 occasions. Eight electrodes were recalibrated, 7 once, one twice. Mean time between calibrations was 38 hours.

Fig. 1 shows the correlation between the Pao_2 values from the blood sample and the meter reading of the Pao_2 electrode (a), at the time of sampling and (b) 45 seconds later.

The relation between Pao_2 recorded by the Radiometer electrode and the catheter electrode is described by the equations:

(a) Simultaneous reading
$y=8{\cdot}35+0{\cdot}86x$ ($r=0{\cdot}867$. SE of regression $=9{\cdot}15$)

(b) Reading at 45 seconds
$y=2{\cdot}29+0{\cdot}97x$ ($r=0{\cdot}948$. SE of regression $=5{\cdot}84$).

The value of Pao_2 read at 45 seconds is a significantly better estimate of the true Pao_2 value ($F=2{\cdot}45$, $P<0{\cdot}001$). When this reading of Pao_2 at 45 seconds (Fig. 1 (b)) is used to predict the true Pao_2 value, the meter reading has 95% confidence limits for regression of ± 11·5 mmHg (1·5 kPa). This compares with a value of ± 17·9 mmHg (2·4 kPa) for the reading in the time of sampling (Fig. 1 (a)).

The differences between individual values for Pao_2 read by the electrode at 45 seconds and the Radiometer Pao_2 value ranged from 0 to ± 21 mmHg (2·8 kPa) within the preset limits of two consecutive values >10 mmHg (our criteria for recalibration). The SD of the differences was ± 5·6 mmHg (0·75 kPa). Fig. 2 shows an example of one electrode's performance plotted to show the variation in the prediction of actual Pao_2 and an example of recalibration. The 95% confidence limits for regression of ± 11·5 mmHg (1·5 kPa) defines the limits that may be used without the need to repeat a blood sample.

Discussion

Continuous recording of Pao_2 in sick newborn infants is potentially a method by which oxygen tension may be kept within safe limits while, at the same time, reducing the number of blood samples taken and hence the need for transfusion of blood.

To achieve this, the electrode when accurately calibrated must remain stable, and the frequency of recalibration be reduced to a minimum. An unduly long response time can lead to incorrect calibration,

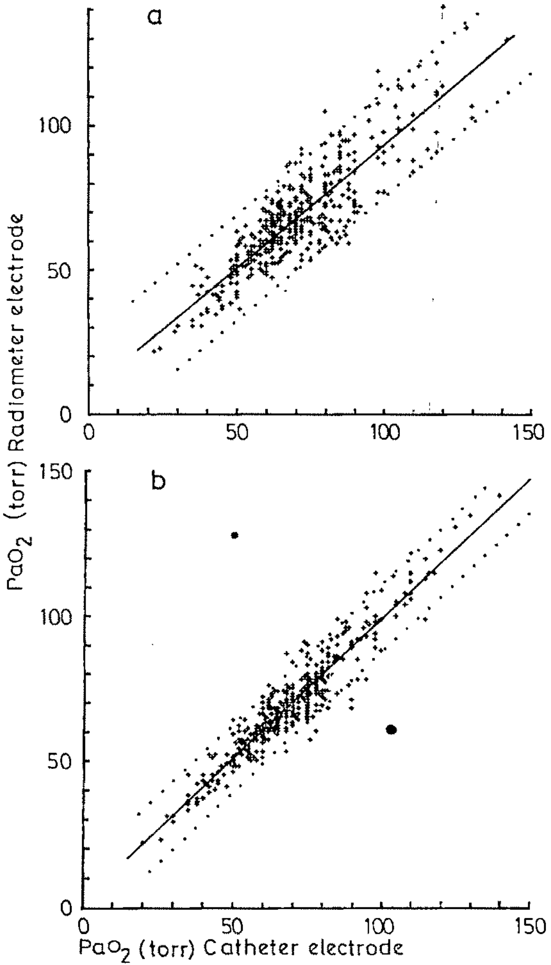

Fig. 1 *Relation between PaO_2 reading from catheter electrode and PaO_2 in a blood sample measured by Radiometer electrode. (a) Electrode reading at time of blood sampling. (b) Electrode reading 45 seconds after blood sampling. 95% confidence limits are shown.*
Conversion: 7·5 torr (7·5 mmHg) = 1kPa.

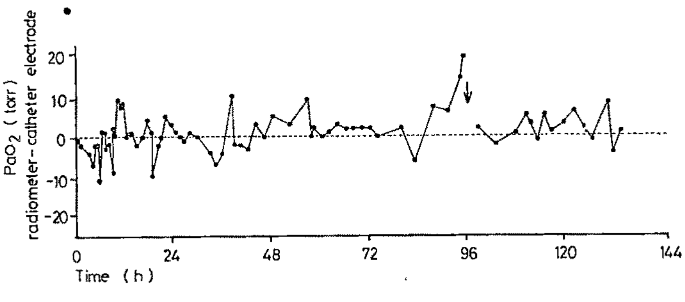

Fig. 2 *Example of sequential difference between PaO_2 reading from catheter electrode and PaO_2 in blood sample measured by Radiometer electrode. Electrode recalibrated at arrow.*

especially if PaO_2 is changing during sampling. In a preliminary study of this problem, Rolfe (1976) using a similar electrode, reported differences of −13 to + 19% despite recalibrating the electrode after each of 6 blood samples during a 3-hour period.

We have shown that greater accuracy and therefore a reduced frequency of recalibration may be obtained by allowing for the response time of the system by reading the meter 45 seconds after blood sampling.

When used in this way recalibration is only required when the meter reading differs from Pao_2 in a blood sample by more than ± 11·5 mmHg (95% confidence).

Haemorrhage responsive to vitamin K in a 6-week-old infant

A. M. B. MINFORD AND O. B. EDEN

Royal Hospital for Sick Children, Edinburgh, and Department of Child Life and Health, University of Edinburgh

SUMMARY A 6-week-old breast-fed infant presented with vomiting, jaundice, and irritability. Haemorrhage occurred after lumbar puncture, and a coagulation abnormality which responded to vitamin K was found. It would seem prudent to estimate the prothrombin time before invasive procedures in breast-fed infants of this age, or to give vitamin K to such infants when doubt exists about previous vitamin K administration.

Case report

A term baby boy weighing 3450 g was delivered after spontaneous onset of labour to a primagravid mother. Apgar scores were 3 at one minute and 5 at five minutes. He was resuscitated with oxygen delivered by face mask. Mild, presumed physiological jaundice developed on day 3 but otherwise the neonatal period was uneventful. Neither mother nor baby received vitamin K. He was breast fed. Slight jaundice persisted after his discharge on day 5 but he remained well until admission at 6 weeks with a 2-day history of nonprojectile vomiting after feeds without haemorrhage. For 5 days there had been slight irritability on handling, but sleep, feeding, and bowel function were all normal. The icterus had intensified. There was no history of maternal or infant drug ingestion, but both parents had developed upper respiratory tract infections 5 days previously.

On admission the baby was afebrile, slightly jaundiced, mildly dehydrated, and irritable on handling. Weight was on the 50th centile with length and head circumference on the 90th centile for age. The anterior fontanelle was full but not tense. Systematic and neurological examination, including fundoscopy, were normal. No clinical evidence of pyloric stenosis was detected. Initial investigations included a haemoglobin of 9·1 g/dl, a white blood count (WBC) of $9 \cdot 2 \times 10^9/l$ ($9200/mm^3$) (neutrophils 35%, lymphocytes 65%), and a platelet count of $360 \times 10^9/l$ ($360\,000/mm^3$). The film contained a few atypical lymphocytes. Serum electrolytes were within normal limits. Serum total bilirubin was 90 μmol/l; 5·3 mg/100ml (direct 39 μmol/l; 2·3 mg/100ml). Full infection screen, including CSF analysis, showed no evidence of a bacterial infection.

Within 8 hours he became pale and lethargic. An extensive haematoma at the lumbar puncture site and oozing from the venepuncture site were noted, but no petechiae or ecchymosis. He remained afebrile. His haemoglobin had fallen to 7·4 g/dl, the WBC had risen to 13·9 × 10^9/l; 13 900/mm^3 (neutrophils 53%, lymphocytes 38%), and the platelets were 450 × 10^9/l (450 000/mm^3). His blood film showed no evidence of red cell fragmentation nor of toxic neutrophil changes. Coagulation screen showed a prothrombin time of 300 seconds (control 13 s), a PTTK of 120 seconds (control 37 s) and serum fibrinogen of 1·7 g/l; (170 mg/100ml). His serum electrolytes were unchanged. The direct Coombs's test was negative and the serum bilirubin was unchanged. Hepatic enzymes showed no increase with an ALT of 49 units/l and an AST of 52 units/l (normal values for each 5–120 units/l). Serum alkaline phosphatase was 599 new units/l. Serum T4 was 150 nmol/l (11·65 μg/100ml). Urine contained no reducing substances and there was no evidence of bacterial or viral pathogens from cultures of urine, stools, blood, or throat and nose swabs. There was no alteration in viral titres to CMV, herpes simplex, rubella, and toxoplasma. He was Australia antigen negative. Maternal prothrombin time was 15 seconds. Treatment included transfusion with packed red cells (80 ml), 2 mg IV vitamin K, and gentamicin, cloxacillin, and IV fluids. Within 12 hours the prothrombin time was corrected to 15 seconds (control 15 s), the PTTK to 34 seconds (control 35 s), and the haemoglobin raised to 10·7 g/dl. There was no other alteration in the coagulation screen. Fibrin degradation products were normal throughout. No further bleeding occurred. Mild fever persisted for some 3 days but without emesis. Weight gain continued with breast feeding and he showed no further clinical or laboratory disturbance of coagulation during the ensuing week. One week after admission serum bilirubin had fallen to 19 μmol/l (1·1 mg/100ml).

Two months later he was thriving with no further haemorrhagic sequelae.

Discussion

This infant presented with vomiting and an increasing jaundice at 6 weeks. No evidence of bacterial infection was found and, although no viruses were isolated, there had been a presumed viral infection in the family and, in addition, atypical lymphocytes were seen on the blood film.

The prolonged neonatal jaundice may have been related to breast feeding or liver immaturity but normal liver enzymes excluded gross hepatic disease. There was no evidence of congenital infection galactosaemia, or hypothyroisidm. The jaundice may have been exacerbated by decreased fluid intake, and emesis with the infection.

We presume that the bleeding after lumbar puncture was related to vitamin K deficiency in view of the prolonged prothrombin and partial thromboplastic times and their rapid correction with vitamin K.

Normal platelet counts, serum fibrinogen, fibrin degradation products, and blood film excluded a consumptive coagulopathy. There was no maternal history of any drug ingestion.

In classical haemorrhagic disease of the newborn, bleeding occurs as a result of deficiency of vitamin K-dependent clotting factors and is virtually confined to breast-fed babies. It is preventable if vitamin K is given at birth. A haemorrhagic syndrome with a similar coagulation abnormality occurs beyond the neonatal period, usually between 4 and 12 weeks.

Factors which have been previously implicated are: (1) decreased vitamin K intake due to breast feeding; (2) prolonged diarrhoea; (3) antibiotics causing an alteration in gut flora. Nammacher *et al.* (1970) described 4 such infants aged between 5 and 8 weeks. None had been given vitamin K at birth and 3 were breast fed; 2 had intracranial bleeding and the coagulation abnormality was corrected with vitamin K in all 4. Other cases have been similarly described in association with diarrhoea and antibiotics (Goldman and Deposito, 1966).

In this case, the baby had not received vitamin K at birth and was entirely breast fed with a presumed defective vitamin K intake. Breast milk contains 15 μg/l vitamin K whereas cows' milk has a higher level of 60 μg/l. He had not been given antibiotics nor had he had diarrhoea. It would appear that breast feeding alone was responsible for his vitamin K deficiency state, and perhaps the coagulation abnormality would not have come to light had he not developed an infection necessitating lumbar puncture and venepuncture.

We thank Dr D. G. D. Barr for permission to report this case.

Cervical lymphadenitis in childhood due to mycobacteria of the Fortuitum group

MARILYN J. RIVRON, E. A. HUGHES, J. R. SIBERT, AND P. A. JENKINS

Welsh National School of Medicine, the University Hospital of Wales, Cardiff, and the Mycobacterium Reference Unit (PHLS), Cardiff

SUMMARY Two children with cervical lymphadenitis due to *Mycobacterium fortuitum* infection are described; both presented with erythema nodosum.

Opportunist mycobacteria which grow rapidly at 37 and 25°C and lack pigment, belong to the Fortuitum group (Marks, 1976). Infection is rare in man and it usually follows injections (Beck, 1965) or trauma (Hand and Sanford, 1970). We report 2 children presenting with cervical lymphadenitis and erythema nodosum due to Fortuitum group organisms. This has not been previously reported.

Case reports

Case 1. A 5-year-old girl from mid-Glamorgan presented in November 1977 with bilateral cervical swellings fluctuant on the left, fever, and erythema nodosum. There was no family history of tuberculosis. The Mantoux test with 1 TU PPD was strongly positive but *x*-rays of the chest were normal. The left-sided cervical abscess was incised and drained (Mr J. Lari). The pus showed numerous acid- and alcohol-fast bacilli on microscopical examination and within 7 days an organism belonging to the Fortuitum group was grown. It was resistant to all antibiotics except ethionamide, gentamicin, and amikacin. Initially the patient's condition improved after operation on standard antituberculous treatment (rifampicin, isoniazid, and ethambutol). However, the fever returned and she developed an abscess on the right. This was incised and drained (Mr J. Lari), and the treatment changed to ethionamide 125 mg twice daily, and gentamicin 40 mg three times daily, the latter for 10 days. She became afebrile on this regimen and the swelling subsided. She remains on ethionamide. Curettings of the right-sided abscess showed poorly-formed and ill-defined granulomata.

Case 2. A 5-year-old girl from Cardiff presented in January 1978 with a right-sided submandibular swelling and erythema nodosum, She had had a dental extraction 6 months earlier. However, *x*-rays of the mandible and chest were normal. The Mantoux test with 1 TU PPD was strongly positive. The swelling which was an enlarged lymph gland was totally removed (Mr J. Lari). Fortuitum group organisms resistant to all antibiotics except ethionamide, gentamicin, and amikacin were grown. The wound healed and the swelling has not recurred despite the patient being managed without antibiotics. ESR has fallen from 70 mm in the 1st hour and her erythema nodosum has resolved.

Lipid analysis of the two strains showed that one (Case 2) was identical with *M. fortuitum* NCTC 10394 while the other (Case 1) had a slightly different lipid pattern (Marks and Szulga, 1965).

Discussion

Children are constantly exposed to opportunist mycobacteria present in the environment. The organisms most likely to cause cervical adenitis are either *Mycobacterium avium* or *Mycobacterium intracellulare* species, but the presentation of these two children shows that *M. fortuitum* and other species must also be considered. Fortuitum group mycobacteria have been cultured from the sputum of approximately 25% of Welsh miners without immediate illness appearing to result (Jenkins and Marks, 1971), and the organisms must therefore be common. In Case 1 there was no apparent portal of entry; the dental extraction was probably significant with Case 2.

The high degree of resistance of the organism to antibiotics presents difficulties in the management as ethionamide is the only oral medication to which these mycobacteria are sensitive. Case 2 was managed without antibiotics as the gland was totally removed, but the widespread tissue involvement in Case 1 warranted chemotherapy.

We thank Professor O. P. Gray, Dr C. M. Weaver, and Mr J. Lari for permission to publish these cases.

Progressive hypogammaglobulinaemia in a child born to a mother with Hodgkin's disease

D. I. K. EVANS AND J. L. BURN

Departments of Child Health and Haematology, Royal Manchester Children's Hospital, and Bolton General Hospital, Lancashire

SUMMARY A young woman developed Hodgkin's disease (nodular sclerosis) in pregnancy and gave birth to a boy who developed common variable immunodeficiency. Initially there was normal IgG with low IgA and IgM, and antibody deficiency. IgG levels fell progressively over 4 years. Cellular immunity was normal. We suggest that this is a further family with immune deficiency presenting with common variable immunodeficiency and lymphoid malignancy.

The association of immunodeficiency with lymphoid malignancy has been reported. We report an unusual combination in a family: a young woman developed Hodgkin's disease in the 3rd trimester of pregnancy and gave birth to a boy who was found later to have common variable immunodeficiency. The father and elder child are normal.

Case histories

The mother. The mother's past medical history was uneventful until her appendix was removed for acute appendicitis at 28 years; during convalescence she developed infective hepatitis.

She noted enlarged cervical lymph nodes during her normal 2nd pregnancy at age 29. A month after confinement she developed a large liver and spleen. A lymph node biopsy showed Hodgkin's disease (nodular sclerosis). She also had lymphopenia ($0\cdot38 \times 10^9/l$). She was treated with radiotherapy and chemotherapy but died 4 years later after a generalised herpes zoster infection.

Lymphocyte counts during remission were often $<1\cdot5 \times 10^9/l$ and usually $<1\cdot0 \times 10^9/l$. No other tests of immunological function were done.

The child. Her son was born normally at term weighing 3·23 kg. He was bottle fed. Growth and development in infancy were normal. He received 3 doses of triple antigen (diphtheria/pertussis/tetanus) and oral polio vaccine during the 1st year of life, and a booster at 18 months. Since then he has had chicken pox and mumps. He has had recurrent nasal discharge, fever, nocturnal cough, occasional wheezing and exertional dyspnoea, intermittent diarrhoea, and two attacks of pneumonia, associated with neutrophil leucocytosis.

At age 5½, he developed herpes zoster. Apart from mild superficial scarring, there were no sequelae. Serum immunoglobulin concentrations were IgG 6·0–6·2 g/l, IgA 0·12 and $<0\cdot10$ g/l. IgM was not detectable. Finger clubbing, a prominent sternum, and persistent coarse adventitial sounds over the right middle lobe were noted. Tonsils and adenoids were very small. He had no lymphadenopathy or enlargement of liver or spleen. *X*-ray showed chronic inflammatory changes in the right upper and lower lobes suggesting bronchiectasis.

At age 6 years, haemoglobin was 11·2 to 12·4 g/dl, with WBC $10\cdot7$ to $12\cdot4 \times 10^9/l$, neutrophils 62%, lymphocytes 33%, monocytes 3%, eosinophils 2%. The absolute lymphocyte count was approximately $4\cdot0 \times 10^9/l$, small lymphocytes 42%, medium lymphocytes 44%, large lymphocytes 14%. Tests of immunity are shown in the Table.

The neutrophil NBT test showed 3% positive cells

Table *Immunological investigations at age 6 years*

Skin tests for delayed hypersensitivity (48 hours)			
Mumps		5 mm

Pokeweed mitogen	16–50 000		30–50 000
Immunoglobulins			
Serum IgG 6·9 g/l			
IgA not detected			
IgM not detected			
IgE 220/ng/l			

in the resting state, and 72% after latex phagocytosis.

The saliva contained IgG 0·16 g/l and IgA 0·5 g/l. IgM was not present, but free secretory component was detected. The serum IgG showed a reversal of the normal 2:1 kappa to lambda ratio, and was short on immunoelectrophoresis. No antibodies to milk products were present. No antibody was detected to rubella, measles, cytomegalovirus, varicella, mumps, polio type 2, or pertussis. Antinuclear factor was negative.

The blood group was O Rh (D) positive. No anti-A or anti-B was present. The HLA type was A1, A3, B5, B7. The direct antiglobulin test was negative. The bone marrow contained 30% lymphocytes, mainly small forms. No plasma cells were seen in over 1000 cells.

An inguinal node biopsy was taken after a booster dose of diphtheria/pertussis/tetanus into the anterior surface of the right thigh. The node was small and dissected with difficulty. There was little surrounding fibrosis. Cortical lymphoid tissue was sparse with very poor follicle formation and no reacting centres. The paracortical area was normally cellular. Macrophages were present in the peripheral sinuses.

Total haemolytic complement was normal, with normal C1 inhibitor and C1q. C3 was 0·85 g/l and C4 0·3 g/l. No virus was isolated from faeces, but adenovirus type 7 was isolated from a sputum sample on one occasion. Bacterial cultures of sputum grew *Haemophilus influenzae*. On a fat intake of 50 g/day for 3 days the faeces contained 4·5 g fat, i.e. 97% absorption.

Regular postural drainage and injections of immunoglobulin were started.

After a loading dose of 5 days' gammaglobulin, the serum IgG levels rose by the expected amount to 8·5 g/l, but on weekly maintenance, levels have progressively declined by approximately 1·0 g/l per year and have remained at 3·0–4·0 g/l during the last year with continued maintenance. IgA and IgM have not shown any significant changes. IgG was present in the saliva at first, but later became undetectable. There has been no change in the salivary IgA deficiency.

During 4 years of observation, sputum production, chest rales, and finger clubbing have regressed considerably. The chest *x*-ray is now normal. There has been intermittent alopecia areata, and a traumatic synovitis of the hip.

He is growing normally and doing well at school.

Discussion

The patient's immunodeficiency, with normal IgG, deficient IgA and IgM, and antibody deficiency, was at first similar to the case of Giedion and Scheidegger (1957), but without the profound defect of cellular immunity. However, IgG levels fell progressively during treatment with gammaglobulin, and salivary IgG also became undetectable. Skin tests showed positive but weak delayed hypersensitivity, and no conclusive defect of cellular immunity could be shown. B-cells were normal or raised, whereas in sex-linked gammaglobulinaemia they are usually reduced (Cooper and Lawton, 1972). Such patients are now grouped under common variable immunodeficiency. Although the progressive fall of IgG is unusual, it might be found in a larger number of cases if investigations were made early enough. An alternative explanation is that this IgG without detectable antibody activity has been suppressed by replacement with normal antibody.

The alopecia was attributed to trichitillomania, as he has been observed to pull his hair; but it may be a further example of the alopecia associated with hypogammaglobulinaemia described by Ipp and Gelfand (1976).

The mother's disease was histologically nodular sclerosis, the common type of Hodgkin's disease in young women. Lymphopenia is a common feature of Hodgkin's disease. However, Hodgkin's disease in pregnancy is not normally associated with illness in the baby. Poliwoda *et al.* (1967), in an extensive review, reported that 151 of 162 children born to mothers with Hodgkin's disease were normal. Six were stillborn and 10 died within a few hours or before they were three. Follow-up of such children has concentrated on the development of Hodgkin's disease, and not on immunodeficiency. However, these authors noted that one mother had two boys who both died, one with pneumonia and the other with obscure pyrexia and collapse, which could indicate a familial defect of immunity.

We do not attribute our patient's illness to his mother's illness, but there is a well-known association between immunological abnormality and malignancy. Several families have been described with a high incidence of Hodgkin's disease or lymphoma and immunological defect (Potolsky *et al.*, 1971; Buehler *et al.*, 1975). There must be a genetic basis for this combination of disorders in some families, although the occurrence of Hodgkin's disease in husband and wife (Mazar and Straus, 1951) suggests an environmental cause in others. In our case we believe that one genetic defect of immunity has predisposed to malignancy and immunological deficiency.

We thank Dr R. A. Thompson for immunoglobulin estimations and for supplying replacement gammaglobulin, and Dr S. Kumar for tests of lymphocyte markers. Miss V. Rawlinson kindly measured serum complement.

Intrapartum sensitisation of human infants to the Rhesus-D antigen

COLIN M. STERN

Department of Paediatrics and Neonatal Medicine, Hammersmith Hospital

SUMMARY A study is reported of the numbers of nonimmunoglobulin-bearing lymphocytes specifically binding to Rhesus-D positive erythrocytes in the blood of Rhesus-dd infants born to either Rhesus-dd or Rhesus-Dd mothers, at birth and at 6 months of age. There was a significant increase in the number of such antigen-binding cells by age 6 months in babies born to Rhesus-Dd mothers. It is concluded that the Rhesus-negative offspring of Rhesus-positive mothers may be sensitised against the Rhesus-D antigen at birth and that protection of such female infants by the injection of antiRhesus-D antibody should be considered.

The human infant at birth is capable of humoral antibody production against specific antigens. Although these responses are almost confined to immunoglobulin M (IgM) production, small amounts of immunoglobulin G (IgG) can be detected. Immune responses to most antigens require T-lymphocyte help and therefore the presence of specifically reacting T-lymphocytes. The response to the Rhesus-D (Rh-D) antigen is thought to be of this kind.

Since the introduction of treatment with pooled antiRh-D antiserum for Rh-dd mothers postnatally, the incidence of haemolytic disease of the newborn has fallen dramatically. A few new patients are still found, usually ascribed either to the injection or infusion of Rh-incompatible blood or to a failure in treatment with antiRh-D antiserum (Woodrow, 1974). Some studies have suggested, intriguingly, that the birth of a Rh-dd infant to a Rh-Dd mother could lead to intrapartum sensitisation of the offspring, whose latent sensitivity might be reactivated many years later, during the gestation of a Rh-D-positive fetus. Ramos de Almeida and Rosado (1972) found that the incidence of rhesus isoimmunisation by birth rank was dependent upon the grandmaternal Rh blood group, while Taylor (1967) and Hindemann (1973) suggest that sensitisation against Rh-D in infancy may be a significant event.

Some Rh-dd male infants, the offspring of either Rh-dd or Rh-Dd mothers, were selected by the Rh blood group and the ability of their peripheral blood lymphocytes to bind to Rh-D-positive erythrocytes at birth, and at 6 months, was studied.

Materials and methods

Blood samples were obtained from infants via the umbilical cord at birth and by venepuncture from the same infants at 6 months. The cells were purified by density centrifugation (Böyum, 1968) and washed 3 times in Eagle's minimal essential medium buffered with hepes (MEM-hepes). Indicator erythrocytes were either washed in MEM-hepes 3 times before use, or were first treated with a subagglutinating dose of $F(ab')_2$ (Nisonof *et al.*, 1960) antiRh-D antiserum and then washed 3 times in MEM-hepes. Both preparations were made as 1% suspensions in MEM-hepes. The indicator erythrocytes* had been screened for a battery of red cell antigens and known to be positive only for Rh-D, although the presence of other blood group antigens could not be completely excluded.

Equal 50 μl volumes of the lymphocyte suspension, at $2 \cdot 5 \times 10^9$/l (2500/mm^3), and either indicator erythrocytes or indicator erythrocytes previously treated with antiRh-D antiserum, were mixed, centrifuged at 250 *g* for 7 min at room temperature, and incubated at 37°C for 30 min. 50 μl of MEM-hepes containing fluorescein di-acetate (Bodmer *et al.*, 1967) was added, and the numbers of fluorescent rosetted lymphocytes counted under a Leitz Ortholux fluorescent microscope. Control studies, in which lymphocytes had been pretreated with a $F(ab')_2$ antihuman immunoglobulin antiserum, showed that about 5% of rosettes were inhibited in this way, so that most antigen-binding cells (ABC) were non-immunoglobulin-bearing and therefore were probably T-lymphocytes.

Results and discussion

The results in the Table show the numbers of Rh-D-specific ABC detected per 10^6 lymphocytes. The values are derived by subtracting the numbers of rosettes formed after treatment of indicator erythrocytes with $F(ab')_2$ antiRh-D antiserum from the number of rosettes formed without erythrocyte pretreatment, leading to a number of negative values. Although no circulating ABC binding Rh-D antigen were found in cord blood at birth in either group of babies, by age 6 months 6 of 10 infants born to Rh-Dd mothers showed significant numbers of ABC and 2 more infants in the same group showed a smaller rise. Only 2 infants showed no increase in ABC. Three of 12 infants born to Rh-dd mothers demonstrated a small rise in ABC.

Table *Rhesus D antigen-specific rosettes per 10^6 cells formed by cord blood and peripheral blood lymphocytes from Rhesus D-negative infants of Rhesus D-positive and Rhesus D-negative mothers at birth and 6 months of age*

11	—	−3	—	−3
12	—	0	—	−4
Probability of difference between groups (Whitney-Mann)	Not significant		Significant at 2% level	

Values for both groups were compared by a Mann-Whitney U test (Mann and Whitney, 1947), which confirmed the similarity between the two groups at birth, but showed a difference, significant at the 2% level, between the two groups at 6 months. These results support the clinical evidence of the effect of the grand-maternal Rh blood group on the incidence of haemolytic disease of the newborn and provide evidence for the intrapartum sensitisation of Rh-dd newborn infants against the Rh-D antigen by transplacental haemorrhage from their Rh-Dd mothers. It may be that, if there is to be a reduction in the small number of mothers where the injection of antiRh-D antibody 'fails' to protect against Rh isoimmunisation, consideration should be given to the protection of Rh-dd infant girls born to Rh-Dd mothers by injection of antiRh-D antibody.

Fetal growth and parental consanguinity

J. R. SIBERT, MALATI JADHAV, AND S. G. INBARAJ

Christian Medical College, Vellore Tamil Nadu, South India

SUMMARY Anthropometric measurements made on 322 newborn infants in South India were related to parental consanguinity. Uncle-niece and first-cousin marriages were common and the average coefficient of inbreeding was as high as 0·0329. The measurements (weight, length, head circumference, and triceps and subscapular skinfold thicknesses) of the uncle-niece groups (52 infants) were smaller than those of the first-cousin group (61 infants) which in turn were smaller than the nonconsanguineous group (196 infants). Statistical significance ($P<0 \cdot 01$) was only recorded between the weights of the three groups (means 2650·4, 2794·1, and 2833·8 g) and between the lengths of the uncle-niece group and the nonconsanguineous group (means 46·92 and 47·79 cm). There were no social class or residential differences between the groups. We conclude that there are likely to be recessive genes present in the population, slightly retarding fetal growth.

There are probably more consanguineous marriages in South India than in any other large nonisolated population in the world. Uncle-niece and first-cousin marriages are favoured for a variety of cultural reasons, including keeping property in the family. In the course of a study to assess the effect of maternal nutrition on infant anthropometric measurements (Sibert *et al.*, 1978), we thought it valuable to assess the effect of parental consanguinity on fetal growth.

Material and methods

Mothers and their babies were studied at two hospitals in Vellore, Tamil Nadu, South India: the Christian Medical College Hospital and the Government Pentland Hospital. All singleton infants over 37 weeks' gestation born on unselected days were studied during the period August to October 1977. As information on gestation was inaccurate in a significant number, all infants were assessed by the method of Parkin *et al.* (1976). All but 8 of them were >39 weeks' gestation. None of the mothers smoked.

Interns from the Child Health Department assisted with Tamil translation. Information was collected on the relationship between the parents. Information was also collected on the social class of the father, whether the parents paid for the care, and whether the family lived in an urban or rural area. Birthweights of the infants were recorded by midwives on beam scales. Anthropometric measurements were made by one of us (J.R.S.) within 36 hours of birth. Crown-to-heel length was measured by Cardiff neonatometer, and occipito-frontal head circumference by paper tape measure. Infant skinfold thickness was measured by a Holtain caliper (reading to 0·1 mm) at the left triceps and subscapular sites using the methods of Oakley *et al.* (1977).

In the course of the study one stillborn child of first-cousin parents with a form of achondrogenesis was noted but not included in the study. One living microcephalic child of uncle-niece parents was included.

Results

322 infants were studied. The relationship of their parents is shown in Table 1. Over 39% of the children had consanguineous parents. The average coefficient of inbreeding was 0·0329. Of particular note was the

Table 1 *Relationship of the parents of infants*

	No.	*Proportion of population* (P_1)	*Inbreeding coefficient* (F_1)
Uncle-niece	52	0·162	0·125
Cousin			
First	61	0·189	0·0625
First once removed	5	0·016	0·0313
Second	6	0·019	0·0156
Third	2	0·006	0·0039
All consanguineous	126	0·391	
Nonconsanguineous	196	0·608	

Average inbreeding coefficient ($\Sigma P_1 F_1$) = 0·0329

large percentage (16·2%) of uncle-niece marriages. There were no significant differences between the nonconsanguineous and consanguineous groups in social class of the father, whether the parents paid for the care, or whether the parents lived in an urban or rural area.

The means and SDs of the anthropometric measurements of the groups of infants are shown in Table 2. The anthropometric measurements (weight, length, head circumference, and triceps and subscapular skinfold thicknesses) of the consanguineous group as a whole were smaller than the nonconsanguineous group. Nevertheless the weight of the infant was the only parameter in which the differences reached significance ($t = 2{\cdot}11$, $P<0{\cdot}05$). Looking at the consanguineous group in greater detail the measurements of the uncle-niece group were smaller than the first-cousin group and the measurements of this group, in turn, were smaller than the nonconsanguineous group. Significant differences were only shown between the weight of these groups ($P<0{\cdot}01$) and between the length of the uncle-niece group compared with the nonconsanguineous group ($P<0{\cdot}01$).

Discussion

Our study shows that consanguinity contributes to interuterine growth retardation. Studies in Vellore (Rao and Inbaraj, 1977) showed small but significant increases in perinatal mortality with consanguinity. Decreased fetal growth may be one of the mechanisms for this.

Previous studies on birthweight and consanguinity have shown similar findings to ours with small but usually significant changes. Morton (1958), studying Japanese infants, found mean birthweights of 3074 and 3046 g for his unrelated and first-cousin groups. Similar Japanese data were analysed by Slatis and Hoene (1961) and Schork (1964). Fried and Davies (1974), studying the Moroccan-Jewish community in Jerusalem, found the birthweights of infants with uncle-niece parents were lower (mean 3371 g) than those of unrelated parents (mean 3469 g).

Our work, taken in conjunction with these previous studies, suggests that there are recessive genes with a slightly retarding effect on fetal growth present in the general population. Although the existence of recessive genes causing major effects on growth are well known, there is no evidence that they are widely distributed, at least in South India.

Infectious diseases and malnutrition are the main health problems in South India and the effects of consanguinity are relatively small, taking the population as a whole. Nevertheless we have seen many tragedies in consanguineous marriages with as diverse recessively inherited conditions as thalassaemia, Niemann-Pick disease, and spinal muscular atrophy. We believe that the reduction in the number of consanguineous marriages in South India, particularly those between uncle and niece, will become increasingly important as the burden of infectious disease and malnutrition is brought under control.

We thank the British Paediatric Association and the H. J. Heinz company for funding the fellowship of J.R.S. We also thank Professor S. X. Charles, Head Department of Obstetrics and Gynaecology, Christian Medical College, and Dr K. Kalyaram, District Medical Officer, North Arcot District, Tamil Nadu, for letting us study their patients, and Dr D. P. Davies and Mr R. Newcombe for their help.

European Society for Paediatric Nephrology

Twelfth Annual Meeting, Israel, 17-22 September 1978

Amyloid nephropathy in familial Mediterranean fever. D. Zemer, M. Pras, and H. Boichis. Tel-Hashomer. Israel.
Familial Mediterranean fever, common among Sephardic Israelis, usually starts in childhood, with a 90% mortality by age 40, mainly from amyloid nephropathy. Of 1000 patients given daily colchicine since 1972, none of the 968 who had no proteinuria initially has developed amyloid. Of 32 nephropathic patients treated for 2 years, the condition of 14 has improved, 6 remain static, and 12 have deteriorated.

Nephronophthisis (N): a review. A. Drukker. Jerusalem, Israel.
Nephronophthisis (N) and medullary cystic disease are probably one disease. Genetic differences remain unclear because criteria for the heterozygous state are lacking. N is not a primary cystic but a renal interstitial disease. Morphological and functional evidence favour a primary tubulopathy, perhaps proximal. A co-operative effort is needed to evaluate the origin of N.

Ocular abnormalities in nephronophthisis (N). Th. Lennert, K. Scharer, and M. Brandis. Berlin, Heidelberg, and Hannover, FRG.
10 of 20 cases of nephronophthisis (N) showed ocular abnormalities; 5 had tapeto-retinal degeneration, 3 nystagmus, 2 amblyopia, 1 cataract, 1 strabismus, 1 myopia, and 1 hypertensive retinopathy. Autosomal dominant inherited medullar cystic disease (MCD) is not associated with eye abnormalities. N is indistinguishable from Senior-Loken syndrome but may be different from MCD.

Epidemiology of kidney diseases in Finland in 1970-74. R. Lappi. Helsinki, Finland.
All patients treated in hospital in 1970-74 were analysed; 3 patients per 100 000 population had urinary disease; 12% were < 15 years of age, and 6% <5 years. 90% of all patients had pyelonephritis or urological disease, but nephrosis, nephritis, and congenital malformations were more common in children.

Risk factors for cardiovascular diseases in children. F. Dorner, A. Spahr, R. Gautier, and J. P. Guignard. Lausanne and Sion, Switzerland.
1000 children aged 5, 7, and 10 years and 200 parents were examined. Obese children had higher blood pressures (BPs) than controls; no correlation between hypercholesterolaemia and BP was found. BPs were higher in parents of children with raised diastolic BPs. No severe hypertension was found; 5·2% of children had proteinuria and 1·9% had haematuria. Routine screening is unjustified but obese children and those with a family history should be examined.

'Compensatory hypertrophy' of renal size in children with chronic pyelonephritis and unilateral renal damage. I. Claësson, B. Jacobsson, and J. Winberg. Gothenburg, Sweden.
26 randomly selected children with unilateral renal scarring from chronic pyelonephritis were followed up for 11 years. 16 had compensatory hypertrophy of the contralateral kidney but ipsilateral hypertrophy after damage was rare. Estimates of total renal area from radiographs suggested that the hypertrophy compensated for much of the renal damage and this compensatory growth accelerated in adolescence.

Syndrome of inappropriate ADH secretion in mechanically-ventilated newborn infants. J. Nutman, E. Wilunsky, and S. H. Reisner. Petah Tiqva, Israel.
Three of 106 infants admitted to the neonatal intensive care nursery over 6 months had the syndrome of inappropriate ADH secretion diagnosed from hyponatraemia, weight gain, and highly concentrated urine. All were on mechanical ventilation, onset was rapid, and deep coma occurred in one infant. Fluid restriction and sodium replacement led to rapid improvement.

Cellular localisation and time course activity of alkaline and acid phosphatases in the nephrotic rat kidney. J. J. Helwig, C. Bollack, and J. Geisert, Strasbourg, France.
Nephrotic syndrome was induced by puromycin injection, proteinuria occurred on day 5 and was maximal on day 9. Alkaline phosphatase in tubules and medulla rose on day 1 and was at its maximum on day 5, but was unchanged in glomeruli and cortex. Acid phosphatase was greater in glomeruli on day 1 but rose on days 6 and 7 in glomeruli and

tubules. It is not clear whether these changes correlate with the renal disease or are a clinical effect of puromycin.

Renal cystic disease. J. Bernstein. Michigan, USA.
Infantile polycystic disease (IPCD) and adult polycystic disease (APCD) may present at birth but can be distinguished clinically, radiologically, morphologically, and genetically. The hallmark of IPCD is medullary ductal ectasia, and in APCD there is irregular cyst distribution with severe glomerular involvement; cysts are commonly surrounded by smooth muscle fibres. Cysts may be secondary manifestations of heritable metabolic defects rather than inherent themselves. Tuberose sclerosis is an important differential diagnosis in a child with cystic disease.

Podocyte degeneration in glomerular disease. J. Churg and E. Grishman. New York, USA.
Degeneration of glomerular epithelial cell podocytes is common in many renal diseases. Either the original cell or a new cell can regenerate, adding in a haphazard fashion to the thickness of the basement membrane. Similar changes are seen in animals given puromycin or diacetylbenzidine, suggesting that podocyte damage is of toxic origin; impairment of capillary circulation may be a factor. The denudation of the basement membrane may account for the proteinuria.

Recent advances in congenital nephrosis of Finnish type (CNF). J. Rapola. Helsinki, Finland.
The incidence of congenital nephrosis of Finnish type (CNF) in Finland is 12 per million population per year and 6-8 new cases occur annually. Amniocentesis was performed on 23 'at risk' pregnancies, and in 7 patients, raised levels of amniotic alpha fetoprotein were found. Electron microscopical examination of kidneys from the aborted fetus confirmed the diagnosis in each case. Glomerular basement membranes in CNF show a decrease in collagen and 3-hydroxyproline of collagen, but the significance of these changes is not yet understood.

Prognosis of haemolytic-uraemia syndrome in children. M. F. Gagnadoux and R. Habib. Paris, France.
Between 1967 and 1976, 71 children with haemolytic-uraemia syndrome were studied. The incidence of terminal renal failure was 12% in infants and 54% in older children. Renal biopsy within one month of onset and a year later in 22 children showed that prognosis was related to the number of glomeruli affected and whether the child had cortical necrosis; the development of severe hypertension correlated with the severity of vascular changes. The biopsy appearances were unique with progression to sclerosis of affected glomeruli.

Incidence, primary renal disease, and growth of children less than 5 years of age treated by regular dialysis and transplant. K. Scharer. Heidelberg, FRG.
87 children less than 5 years at start of treatment were registered with the EDTA (European Dialysis and Transplant Association) in 1977. Survival at one year was 90% and at 2 years it was 77%, similar to older children. Nearly half the children lived in France and accounted for 10% of children treated there. Haemolytic-uraemia syndrome and cortical necrosis were important causes of renal failure. Growth was similar to that of older children.

Amino-acid metabolism and growth in infants with chronic renal failure. C. Giordano. Naples, Italy.
Daily weight gain was studied in infants with chronic renal failure on low-protein diets with supplements of different essential amino-acids (EAAs) and keto-acids. Marked improvement was demonstrated especially with EAAs but the formula of the EAA supplement used was critical.

Carbohydrate and lipid metabolism in chronic renal failure. C. Chantler. London, UK.
Energy metabolism is disturbed in renal failure with failure of normal glucose metabolism leading to potential cellular energy deficiency, protein malnutrition, and hyperlipidaemia. Low-protein diets with amino-acid supplements theoretically may ameliorate this but must be supplemented with energy; polyunsaturated fats should be used to reduce carbohydrate intake if hyperlipidaemia occurs.

Survey of the experience of the French paediatric units with dialysis and transplant programmes in children under 5 years of age. M. Broyer. Paris, France.
Since 1969, 32 children (4 months–4½ years) have been accepted for dialysis and transplant programmes in 6 paediatric units. Chronic haemodialysis (CHD) was generally performed with radial or humeral internal fistulae. Chronic peritoneal dialysis (CPD) was used alternately with CHD when vascular access was not available. 11 cadaver kidney transplants were done. 11 children have died, 9 are living with kidney transplants, 10 remain on CHD, and 2 on CPD at home. Survival was 74%, 70%, and 62% at 1, 2, and 3 years.

Renal transplantation in children aged 1 to 5 years. S. M. Mauer. Minneapolis, USA.
Results of renal transplants in young children are sufficiently good compared with children of other ages for treatment to be offered to such children.

Incidence of chronic renal faliure in Swedish children. I. Helin and J. Winberg. Malmo, Stockholm, Sweden.
To be published in full elsewhere.

Dialysis bone disease in childhood: treatment with 25 hydroxycholecalciferol (25OHD3). R. Dumas, J-Cl. Luciani, and P. Meunier. Montpellier, France.
Five children on haemodialysis were treated with 25 OHD_3. Plasma calcium rose excessively in one child; growth velocity, plasma parathyroid hormone levels, and histological lesions of osteitis fibrosa cystica were unchanged. The osteomalacia present in one child improved and in 2 children a decrease in trabecular bone volume was observed.

Effects of various protein diets on growth, renal function, and survival of uraemic rats. I. Salusky, C. Kleinknecht, and M. Broyer. Paris, France.
Low-protein diet has been incriminated in growth failure in ureamia. In uraemic rats, high-protein diets (37%) and (27%) had deleterious effects on growth and survival, and led to progression to renal failure, compared with a diet limited to minimal requirements (14%). It is important to avoid any protein excess in chronic uraemia.

Effect of anabolic steroids on growth in boys with chronic renal failure on haemodialysis. J. E. Carter, J. Burke, M. El-Bishti, R. Counahan, V. Wass, N. Dalton, and C. Chantler. London, UK.
Nine boys were treated with oxandrolone; in one the drug was stopped because of a rise in liver enzymes. Height velocity improved significantly and the children grew more rapidly than the advance in bone age. Intracellular water (cell mass) increased. Improvement in glucose tolerance and plasma branch chain amino-acids was observed.

Delayed puberty in males with chronic renal failure. P. Saenger, J. Ferraris, L. S. Levine, S. Pang, M. I. New, and J. E. Lewy. New York, USA.
31 boys aged 11 to 20 years were studied. Testosterone, dehydrotestosterone, and luteinising hormone levels were appropriate for pubertal status, suggesting normal Leydig cell function and activity of 5 α reductase enzyme. FSH levels were raised, suggesting damage to germinal eptihelium but they became normal after successful transplants.

Serum ferritin (SF) concentrations in children with chronic renal failure. D. E. Muller-Wiefel, E. Wolf, D. Schönberg, and K. Schärer. Heidelberg, FRG.
Serum ferritin (SF) levels were determined in 32 children with chronic renal failure, 9 children on dialysis, 8 children with transplants, and 25 controls. The level of SF was raised in all groups compared with controls. SF should be measured before starting iron treatment in children with renal failure because few of them are iron deficient.

Echocardiographic investigation of cardiac action during haemodialysis of children. J. R. Pfefferkorn, L. Diekmann, and U. Schulten-Baumer. Munster, FRG.
12 children on regular haemodialysis were examined. All showed increases in interventricular septum and posterior left ventricular wall due to myocardial hypertrophy. End diastolic diameter of left ventricle was increased, suggesting dilatation, but this decreased significantly during dialysis with fluid removal.

Dialysis and transplantation results in Europe 1977: review of the data from the paediatric registry of the EDTA. R. A. Donckerwolcke, C. Chantler, F. P. Brunner, H. J. Gurland, R. A. Hathway, C. Jacobs, H. Brygner, N. H. Selwood, and A. J. Wing. Holland, UK, Switzerland, FRG, France, and Sweden.
Results were published in *Proceedings of the European Dialysis and Transplant Association*, Volume 15, (1978) Pitmans Medical: London.

Mediation and effects of intrarenal fibrin deposition. P. F. Naish. Stoke, UK.
Intrarenal fibrin deposition may result from primary glomerular inflammation, or microvascular damage with or without intravascular coagulation. Defibrination is associated with protection from glomerular damage. Studies in nephrotoxic nephritis and endotoxin infusion in rabbits indicate the central role of neutrophils in fibrin deposition. Studies of neutrophils, platelets, and coagulation in patients may enable rational treatments to be developed.

Platelets and glomerulonephritis. J. S. Cameron. London, UK.
Platelets are important in the pathogenesis of glomerular damage from chronic soluble complex disease; antiplatelet agents may have a role in treatment but more studies using new tests of platelet function—such as serotonin levels—are needed to confirm this.

Combination therapy for mesangiocapillary nephritis in childhood. S. J. Chapman, J. S. Cameron, C. Chantler, and D. R. Turner. London, UK.
11 children with mesangiocapillary nephritis were treated with prednisolone, azothioprine, heparin, or warfarin; 7 children had a significant rise in glomerular filtration rate (GFR), in 2 the declining GFR stabilised, and 2 in terminal renal failure did

not improve. In 2 children there was a rapid fall in GFR after withdrawal of immunosuppression.

Pathogenesis of focal glomerular hyalinosis and sclerosis. J. D. Elema, M. S. Schilthuis, and J. Grond. Groningen, The Netherlands.
From clinico-pathology observations in children with a variety of glomerular diseases and from experimental studies in rats, it is suggested that focal segmental hyalinosis and sclerosis is a nonspecific lesion. Local haemodynamic factors (pressure, flow) and changes related to the existence of nephrosis (hyperlipidemia, hypercoagulability) are pathogenetically involved although to different extents in different circumstances.

Immunological studies in the haemolytic-uraemia syndrome. L. Monnens, M. de Jong, P. van Muster, and J. Molenaar. Nymegen, Amsterdam, The Netherlands. To be published elsewhere.

Renal function and biopsy studies in patients with IgA and poststreptococcal glomerulonephritis. A one-year follow-up. T. Linne, A. Aperia, and O. Broberger. Stockholm, Sweden.
The renal functional changes of IgA and poststreptococcal glomerulonephritis were similar. GFR was depressed initially but became normal during the first months of the disease. The natriuretic response to an isotonic saline infusion was low in the early course of the disease, and took longer to become normal than GFR.

Deficiency of the second component of complement (C2D) with membranoproliferative glomerulonephritis. Recurrence after transplant. C. Loirat, C. Blum, M. Broyer, and M. Levy. Paris, France.
Membranoproliferative glomerulonephritis with subendothelial deposits was observed in a C2D boy without systemic disease. Immunofluorescence showed IgC, C1q, and C4 as granular deposits along capillary walls and within the mesangium. C3 was also deposited along capillary walls. The clinical course was severe. Recurrence of the glomerular lesions was observed 9 months after transplant.

Nonfamilial recurrent haematuria. L. Callis, M. Carreras, E. Vilaplana, and F. Castello. Barcelona, Spain.
Five girls aged 5–11 years had recurrent haematuria. Family history, renal function, complement levels, hearing, and renal biopsy evaluation by light microscopy and immunofluorescence were normal. Electron microscopical examination showed deposits within the basement membrane or thickening of the basement membrane with layering. The latter changes, present in 2 children, may represent a variant of Alport's syndrome.

Nephropathy in cyanotic congenital heart disease. J. P. Dommergues, M. Levy, M. C. Gubler, R. Habib, and V. Courtecuisse. Paris, France.
Three patients with congenital heart disease had a low glomerular filtration rate, haematuria, and proteinuria. Renal biopsy showed mesangial proliferation, and a double contour thickening of basement membrane due to a heterogenous deposit on the endothelial surface. Immunofluorescence was negative. Renal function improved after successful surgery and the glomerular changes disappeared in one case.

Role of circulating immune complexes (IC) in renal disease. R. J. Levinsky. London, UK.
Immune complexes (IC) differ in immunoglobulin class, subclass, size, complement binding, and antigen, and these differences account for the different results of the several tests used for detecting them. Size of IC is important in the pathogenicity of IC in lupus nephritis; the nonlocalisation of IC in steroid-sensitive nephrosis is probably due to the failure of the IC to bind complement. IgA IC are found in Henoch-Schoenlein disease but nephritis only occurs if IgG IC are present as well. The production of different IC may depend on the genetic differences of the host's immune response to antigen and may underlie the susceptibility to disease.

Complement profiles and C3 nephritic factor-like activity (C3NeF-L) in children presenting with acute glomerulonephritis or membranoproliferative glomerulonephritis (MPGN). M. Levy, M. Sich, E. Pirotsky, and R. Habib. Paris, France.
Activation of the classical pathway was demonstrated in acute glomerulonephritis (34 patients) and membranoproliferative glomerulonephritis (MPGN) type 1 (20 patients) with C3NeF-L (*Clinical Immunology and Immunopathology*, 1978, **10,** 477) in 9 and 7 respectively of these patients. Conversely, activation of the alternative pathway was documented in 13 patients with MPGN type 11, 10 of whom had C3NeF-L.

Complement activating factor (C3AF) in membranoproliferative glomerulonephritis. E. J. Lewis, B. G. Bartlow, and J. L. Roberts. Chicago, USA.
A factor capable of activating C3 (C3AF) by the alternative pathway was isolated by cryoprecipitation from a patient with type 1 membranoproliferative glomerulonephritis. Unlike C3 nephritic factor C3AF is not an IgG; it is suggested that C3AF activates C3 by interaction with $\beta 1H$ leading to increased activity of the 'amplification feedback loop'.

Kinetics of glomerular visceral epithelial cell phagocytosis of macromolecular aggregates from the lamina rara externa of the glomerular basement membrane. Z. Sharon and M. M. Schwartz. Illinois, USA.

The sequential intravenous administration of protamine and heparin results in aggregation and deposition of protamine-heparin aggregates (PHAgs) in the lamina rara externa of the glomerular basement membrane. Experiments in rats confirmed that removal of HPAgs is accomplished by epithelial cell phagocytosis by first-order kinetics unrelated to GFR. Epithelial cell removal of immune aggregates may be important in acute poststreptococcal nephritis and perhaps in other glomerular lesions with subepithelial deposition of immune complexes.

Alternate-day v. intermittent prednisone in frequently relapsing nephrotic syndrome. J. Brodehl and H. P. Krohn. Hannover, FRG.

A prospective study was performed in 48 children with frequently relapsing nephrotic syndrome to compare alternate-day prednisone (23 children) (35 mg/m^2 per 48h) with intermittent prednisone (25 children) (40 mg/m^2 in 3/7 days) during 6-months' treatment. Results show that alternate-day prednisone is significantly more effective than equal amounts of intermittent prednisone for preventing patients from relapsing and for reducing the number of relapses.

Spontaneous remission and delayed therapy in steroid-sensitive nephrotic syndrome. R. J. Postlethwaite, I. B. Houston, and P. C. Powell. Manchester. UK.

To be published in full elsewhere.

Nephrotic syndrome. Value of new methods in kidney biopsy specimens. K. Kuehn, M. Brandis, R. Castelucci, and E. Reale. Hannover, Germany.

Ultrastructural investigation by scanning electron-microscopy and freeze-fractured preparations of renal biopsies from children with minimal change nephropathy showed swelling of capillary epithelium, and widening and loss of peripheral foot processes, without real fusion.

Allergo-immunologic testing in children with nephrotic syndrome due to minimal change (MC) and focal glomerular sclerosis (FGS). D. E. Muller-Wiefel, U. Wahn, V. Lenhard, and W. Rebien. Heidelberg, FRG.

Atopic history score and serum IgE levels were similar in minimal change (MC), focal glomerular sclerosis (FGS), and controls, but 4 children with MC had high levels. The proportion of positive prick tests and increased IgE antibodies was similar in the three groups but lymphocyte stimulation was depressed in MC, with intermediate results in FGS. One child with atopic MC, out of 3 desensitised to grass pollen, entered a stable remission, Allergic mechanisms play a role in only a few children with MC.

Nephrotic syndrome associated with tubular disorders in 5 children. Ph. Barthe and F. Bouissou. Toulouse, France.

Five children with steroid-resistant nephrotic syndrome developed mixed tubular acidosis (5/5), hypokalaemia (4/5), glycosuria (5/5), hypophosphataemia (2/5), aminoaciduria (2/5), and tubular proteinuria (2/5). Progression to renal failure occurred and repeat biopsy showed focal glomerular sclerosis.

Distal renal tubular acidosis (DRTA) in 23 infants and children. M. Dechaux, M. Broyer, G. Lenoir, and P. Guesry. Paris, France.

23 infants and children with primary distal renal tubular acidosis (DTRA) were studied; one had bicarbonate wasting, 3 had no systemic acidosis. Deafness was noted in 5. Dehydration and vomiting were early signs, nephrocalcinosis was common with hypercalaemia. Concentrating capacity was reduced in 15 children. Growth improved with treatment. Familial factors were present in 7 children. DTRA is not a homogenous disorder.

Adolescent cystinosis. Case report and review of the literature. G. Knopfle, H-P Weber, and E. Harms. Bonn, Heidelberg, FRG.

Cystinosis was diagnosed in a 13-year-old boy with a Fanconi's syndrome and a glomerular filtration rate of 34 ml/min per 1·73m^2. Growth and development were normal. Progression to renal failure occurred over 5 years. Adolescent cystinosis is associated with glomerular proteinuria, lower intracellular cystine than in the infantile form, and slower progression.

Physical chemical basis of urinary stone disease. W. G. Robertson, M. Peacock, R. W. Marshall, and B. E. C. Nordin. Leeds, UK.

Abnormal crystalluria leading to stone disease results from imbalance between saturation of urine and inhibitory activity which prevents large aggregates; pH, calcium oxalate, acid mucopolysaccharide, and uric acid are important factors in this balance. The relative contribution of these risk factors enables the probability of stone formation in an individual to be calculated.

Idiopathic hypercalciuria (IH)—an old enigma. U.A. Liberman. Petah Tiqva, Israel.

There appear to be 4 varieties of idiopathic hypercalciuria (IH): (1) increased intestinal calcium absorption, (2) decreased tubular calcium reabsorption, (3) normocalcaemic hyperparathyroidism, and (4) decreased tubular phosphate reabsorption. The aetiology of these forms of IH remains obscure.

Idiopathic hypercalciuria in childhood: clinical and metabolic studies. M. Tieder, H. Stark, and R. Shainkin-Kerstenbaum. Beer-Sheba, Israel.

Compared with 10 controls, 3 children with IH demonstrated evidence of: (1) increased intestinal calcium absorption, (2) decreased parathyroid (PTH) and increased calcitonin (CT) activity, (3) low plasma phosphate due to low TmP/GFR (phosphate reabsorption). These suggest that low TmP/GFR is primary, causing low Pp, which stimulates 1.25 $(OH)_2$ vitamin D production and increased Ca absorption. This, with resulting low PTH and high CT, causes hypercalciuria.

Hypercalciuria (HC), nephrocalcinosis, and nephrolithiasis in metabolic disorders. O. Mehls, F. Manz, and H. Schmidt. Heidelberg, FRG.

Hypercalciuria (HC) secondary to hypercalcaemia is seen with vitamin D intoxication. HC due to failure of proximal tubular reabsorption occurs in the Fanconi's syndrome in association with decreased sodium reabsorption; magnesium supplements to correct hypomagnesaemia may cause HC by competing for reabsorption. In renal tubular acidosis HC is secondary to the metabolic acidosis. Hyperoxaluria may cause nephrolithiasis and 5 of 70 children with phenylketonuria (PKU) developed stones; hyperoxaluria occurs in some children with PKU and occasionally with tyrosinosis.

Address of authors may be obtained from Dr C. Chantler, Evelina Department of Paediatrics, Guy's Hospital, St Thomas Street, London SE1 9RT.

Correspondence

Kawasaki disease

Sir,

I read with interest the letter of Morgan and Lynch (*Archives*, 1978, **53**, 916), and should like to report 2 more white children in the UK—one Welsh and one English.

A 6-year-old boy from Anglesey was admitted in June 1978; 2 weeks previously he had developed fever and a blotchy red rash over the face with red macules on the trunk. He was seen by his doctor, diagnosed as having tonsillitis and scarlet fever, and given a 5-day course of ampicillin. His condition did not improve. On the 12th and 13th days of his illness (two days before admission) he developed peripheral limb pain, particularly around fingers, wrists, ankles, and toes. He was febrile, 38·6°C. There was bilateral cervical lymphadenopathy. The throat was inflamed. There was a grade-1 systolic murmur. Swelling of the fingers, hands, and wrists was noted. At this stage no firm diagnosis was made, but 3 days later prominent tongue papillae, oedema proceeding to skin peeling of the hands and feet, and a high ESR (100 mm in the 1st hour) were noted, and the diagnosis of mucocutaneous lymph node syndrome (MLNS) was made. Hb was 10·6 g/dl. Other investigations gave normal results: white blood count, urine analysis and culture, ASO, throat swab, chest *x*-ray, Paul Bunnell test, blood culture, and ECG.

After 18 days' illness his temperature remitted. The skin continued flaking from the periphery for another 2 weeks, but otherwise he was well, and has remained so for the subsequent 5 months.

A 3½-year-old girl from Merseyside on holiday in Wales presented with a 4-day history of fever for which a doctor had prescribed ampicillin. She had experienced a sore throat, a slight cough, and a few loose stools. The day before admission she had developed an erythematous rash with peeling on the face, trunk, and nappy area.

On examination she had a fever of 39·5°C. There was cervical lymphadenopathy, and an erythematous rash on the face, upper trunk, and nappy areas, with peeling around the nappy area. The tongue papillae were unusually and markedly prominent. The throat and ear drums were injected. There was no heart murmur. Hb was 10·8 g/dl, ESR 106 mm in the 1st hour, urine trace albumin, nil sugar, microscopy and culture negative, CSF normal, throat swab negative, ASO 605 units, blood culture negative, plasma Na 128 mmol/l, K 4·8 mmol/l, Cl 98 mmol/l, plasma urea 20 mg/100 ml (3·3 mmol/l), ECG normal, chest *x*-ray normal, C3 complement 1·16 g/l (raised).

Initially the diagnosis was thought to lie between toxic epidermolysis, due to a staphylococcal toxin, and MLNS. Treatment was started with IV fucidin to no effect, the child remaining febrile and ill. On the 8th day of illness, oedema of the extremities developed and peripheral joint arthralgia. On the 9th day the child was transferred to Alder Hey Children's Hospital, Liverpool, under the care of Professor Harris to be closer to her home. The oedema and arthralgia of the periphery subsided quickly, but the skin of the periphery continued to peel for 2 or 3 weeks. She subsequently recovered completely (4 months later).

Acquired toxoplasmosis and acute hemisyndrome in childhood

Sir,

In an article (*Archives*, 1978, **53**, 414) McNicholl and Flynn reported on 9 cases of acquired toxoplasmosis in childhood, 2 of whom contracted an acute hemisyndrome with persisting sequelae. We observed a similar case in a 5-year-old boy who gradually developed hemiplegia over 24 hours (9–10 December 1977). The boy had been treated with penicillin for an otitis media during the preceeding week. On admission he had a complete left-sided hemiparesis, but had neither lymphoglandular enlargement nor chorioretinitis. An acute right carotid angiography, isotope, and computerised axial tomography (CAT) scans were negative. A repeat CAT scan 6 months later was still normal. CSF findings were inconclusive. Improvement was initially rapid but subtotal. Currently, one year later, only a slight left-sided dysfunction and spasticity remains.

The patient is a farmer's boy and had been playing with his cat. Toxoplasma antibody titres in the patient and cat were as shown in the Table:

1978	*5 January*	*February*		*31 May*	*7 August*
		7	*14*		
Patient					
Immunofluorescence					
IgM	128	64			
IgG	1024	1024			
Complement fixation	128	128		32	32
Dye test	1000	4000		500	500
Cat					
Immunofluorescence			1024		
Dye test			≥250		

As both a significant increase in dye test titre and toxoplasma antibodies of the IgM-class were demonstrable, the findings indicated that the patient had ongoing toxoplasmosis. It appears most likely that the disease was acquired from the cat which had high serum levels of toxoplasma antibodies. Trimethoprim-sulphafurazole treatment (6 February–15 May) may have contributed to the rather rapid fall in antibody titres.

Acquired toxoplasmosis has occasionally been identified in acute hemiplegia in childhood (Sabin, 1941; Hedenström *et al.*, 1958; Lelong *et al.*, 1960). Isler (1971) reported only one case of toxoplasmosis (a 12-year-old boy with a left-sided parietal lobe syndrome with a complete restitution) among 116 acute hemisyndromes in children.

Acquired toxoplasmosis may thus occasionally be the cause of an acute childhood hemiparesis. A focal encephalitis may not be envisaged on the CAT scan and the diagnosis should accordingly be looked for by serological and microbiological methods.

Dose of clonidine in alternating hemiplegia

Sir,

My fellow authors and I wish to point out that in our paper (*Archives*, 1978, **53**, 656–659) there is an error (page 658) in the dose of clonidine given to one of the patients. The dose quoted should have read 2·5 μg/kg per day (not milligrams).

Book reviews

Separation and Special Care Baby Units. Clinics in Developmental Medicine No. 68. Edited by F. S. W. Brimblecombe, M. P. M. Richards, and N. R. C. Roberton. (Pp. 113; illustrated + tables. £6.00 hardback.) Spastics International/ Heinemann: London. 1978.

This monograph, edited by two paediatricians and a social psychologist, reviews the evidence on the effects of early separation on children and their parents and discusses admission and discharge policies of special care baby units. Several studies of babies in such units are presented. The project described in most detail is the study of parental visiting of babies admitted to the Exeter unit. It illustrates well how social circumstances and distance influence frequency of visiting. Even in this unit, committed to encouragement of visitors, some parents never came to see their babies. A study from Queen Charlotte's Hospital demonstrates how little contact babies in incubators have with any adult. Unfortunately the number of term babies on lying-in wards observed for comparison was so small that no conclusions about differences can be drawn. A contribution from a paediatrician and nurse describes how efficient medical care can be combined with a sympathetic approach to parents, and introduces the idea of an intermediate care area which does not entail separation. Statistics presented from Exeter show that only a small proportion of handicapped 5-year-old children had passed through the special care baby unit.

While not disputing the need to increase and improve intensive care facilities, the editors criticise the over-enthusiastic admission of babies 'for observation' because of minor symptoms or because their entries into the world were not completely normal. The argument against such unnecessary separation is convincing. It is futile to expect such a practice to reduce mortality or morbidity figures. The experiences of the Cambridge unit demonstrate how the trend towards increased admission rates can be safely reversed. For about 10% of newborns some separation will be inevitable. Much can be done to promote contact between these babies and their families. The special care all babies need is the caring of their parents.

MARGARET A. LYNCH

Shorter notices

Bibliography of Infant Foods and Nutrition 1938–1977. By J. O. Henderson, S. M. Collins, L. L. Muller, and B. S. Harrap. (Pp. 322. Australian $16.00, paperback.) Commonwealth Scientific and Industrial Research Organization: Australia. 1978.

This bibliography gives the authors, titles, references, and abstract numbers of a broad selection of scientific publications from 1938 to mid-1977, mainly from Dairy Science Abstracts (DSA), Nutrition Abstracts and Reviews (NAR), Food Science and Technology Abstracts (FSTA), and Agricola SDI Service (AGRIC) (formerly) CAIN). Papers included emphasise aspects of infant foods in relation to nutrition, but those on specialised aspects of medicine are excluded.

Host Defenses in the Human Neonate. Monographs in Neonatology Series. By M. E. Miller. (Pp. 123; illustrated + tables. £8.10, hardback.) Grune and Stratton: New York. 1978.

This monograph by a respected research worker is concise, readable, and, for the paediatrician, illuminating. The author sets out to examine the interactions of t various components of inflammatory a immune responses, instead of dealing wi the various systems of immunity isolation. He succeeds brilliantly, a provides important food for thought those concerned in the treatment neonatal infection.

Paediatrics. Second edition. By J. Apl (Pp. 453; illustrated. £4.95, limp cove Ballière Tindall: London. 1979.

The first edition of this limp-cover textbook was favourably reviewed *Archives*, 1974, **49**, 163. The format of t second edition is the same and it remai an excellent and readable introduction the concepts and facts of paediatrics the undergraduate student. It has stay reasonably small and reasonably priced.

Rehabilitation of Arm Amputees a Limb-Deficient Children. By Elizab Robertson. (Pp. 209; illustrated + tabl £8.50 hardback.) Ballière Tindall: Lond 1978.

This excellent book embodies unrivalled experience of the former he occupational therapist to the childre unit, Queen Mary's Hospital, Roehampton, and is predominantly about lin deficient children. Every occupatio therapist trying to help even one s child deserves a copy. It is totally practi in approach and in it such things discussed as parental attitudes, as well training, prosthetics, and gadgetry. O gratitude to Elizabeth Robertson sharing her wisdom, and to Act Research for the Crippled Child helping to make it available, lavis illustrated and in hardback, at a barg price!

Reduced Subscription Rates for Junior Hospital Doctors Residents and Interns...

from January 1 1979

Archives of Disease in Childhood

will be available to junior doctors in all parts of the world for a maximum of four consecutive years at REDUCED Annual Subscription Rates. (Thereafter, or when reaching consultant status this special offer will no longer apply.) The following subscription rates apply for the twelve issues published in 1979.

Inland £17.00

Overseas US$40.00

(The full rates are: Inland £28.00; Overseas US$65.50)

The opportunity to subscribe to this journal of international authority and repute at a substantially reduced subscription rate is one not to be missed by junior doctors seeking to specialise in paediatrics.

Please complete the adjacent order form and send for your subscription NOW.

Further order forms can be supplied on request.

PEDIATRIC RESEARCH

Volume 12, No. 10 October 1978

Contents

The Relationship of Amniotic Membrane 11-Oxidoreductase Activity to Lung Maturation in the Human Fetus 957

A. K. Tanswell and B. T. Smith (Kingston, Ontario, Canada)

The findings demonstrate that in pregnancies where the fetus is destined to develop respiratory distress syndrome after delivery, the amniotic membranes are defective in their ability to produce cortisol, resulting in a possible reduction in the amount of cortisol available to the fetal lung during maturation *in utero*.

Cellular and Humoral Immunity in Cartilage-Hair Hypoplasia 961

M. Virolainen, E. Savilahti, I. Kaitila, and J. Perheentupa (Helsinki, Finland)

In an unselected series of 28 subjects with cartilage-hair hypoplasia, almost all subjects had subnormal responses in tests of cellular immunity, although most of them had no apparent unusual susceptibility to infections. This feature was a more constant feature of the syndrome than the hair abnormality.

Salivary Amylase in Cystic Fibrosis: A Marker of Disordered Autonomic Function 967

G. P. Davidson, A. Koheil, and G. G. Forstner (Toronto, Ontario, Canada)

To determine whether an increased salivary isoenzyme activity might be present in cystic fibrosis, these scientists examined total serum amylase and isoenzyme patterns from a series of patients, including cystic fibrosis (CF) patients with and without steatorrhea, patients with exocrine pancreatic insufficiency without CF (Shwachman's syndrome), and a control group who had neither CF nor pancreatic insufficiency.

The Effect of Racemic, D-Propranolol, L-Propranolol, and Practolol on the Response to Cold by the Newborn Rabbit 971

I. Dober, V. Jaszai, T. Heim, and R. D. G. Milner (Pecs, Hungary, Toronto, Canada, and Sheffield, England)

In this investigation the newborn rabbit has been used as a model to investigate the effects of propranolol, the isomers of propranolol, and practolol on the response to cold exposure.

Fetomaternal Potassium Relations in the Rat on the Twentieth Day of Gestation. II. Effects of Maternal Hypocalemia 977

A. G. Fantel (Seattle, Washington)

A study of potassium homeostatis during maternal hyypokalemia was undertaken in potassium-deficient rats on the 20th day of gestation.

Plasma 25-Hydroxyvitamin D in Familial Hypercholesterolemic Children Receiving Colestipol Resin 980

R. C. Tsang, M. S. Roginsky, M. J. Mellies, and C. J. Glueck (Cincinnati, Ohio)

The effects of colestipol, a new synthetic organic bile sequestrant polymer (U26-597A), on vitamin D metabolism have been assessed in children with familial hypercholesterolemia over a 2-year period.

Pulmonary Diffusing Capacity in Lambs During the Early Neonatal Period 983

J. M. Bissonnette, W. H. Drummond, W. K. Wickham, and J. Z. Cronan (Portland, Oregon)

When a rebreathing method to measure pulmonary diffusing capacity in neonatal lambs was employed, a significant increase in diffusing capacity was found to take place in the first day of life.

Distortions in Fetal Growth Standards 987

R. L. Naeye and J. B. Dixon (Hershey, Pennyslvania)

The findings of the present studies indicate that widely used fetal growth standards appear to include measurements from both growth-retarded neonates and from neonates older than their calculated gestational ages.

Maturation of *p*-Aminohippuric Acid Transport in the Developing Rabbit Kidney: Interrelationships of the Individual Components 992

B. R. Cole. J. T. Brocklebank, R. G. Capps, B. N. Murray, and A. M. Robson (St. Louis, Missouri)

This investigation was undertaken to examine systematically the contribution of the individual cellular mechanisms to the reduction on aryl acid excretion in the immature rabbit kidney with *p*-aminohippuric acid being used as the test aryl acid.

Abnormal Colonization of Neonates in an Intensive Care Unit: Means of Identifying Neonates at Risk of Infection 998

K. Sprunt, G. Leidy, and W. Redman (New York, New York)

Results of these studies indicate that serial throat cultures permit selection of the group of Intensive Care Unit neonates at greatest risk of infection and indicate the probable organism from which they are at risk.

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42,** 109; 1973, **48,** 751; 1978, **53,** 441).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged.
(11) From January 1980 references in the text will be numbered. References given at the end of the paper should be listed in the order in which they are first mentioned. The full title of article or book should be given, and the first and last page numbers of the particular paper or chapter. The titles of journals should be abbreviated according to the style used in Index Medicus (see *British Medical Journal,* 24 February 1979, **1,** 532–535).
(12) Summary to be typed on a separate sheet; and it should say what was done and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood,* B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate is £28.00 in the United Kingdom and the Republic of Ireland, and US$65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

Simplicity itself

The Codman Shunt range, available only from Downs, has proved outstandingly popular with British surgeons. Here's why.

UNI-SHUNT*—the unique one piece shunt.
Simple and easy to insert, it's one piece construction reduces the risk of infection and need for revision.

ACCU-FLO*—the guaranteed system which offers complete flexibility.
The Accu-Flo range of shunts offer the surgeon a complete system from which to choose. They are also guaranteed to function at the stated pressure. Renowned for their consistently high quality and low cost—up to 20% less than some competitive products—Accu-Flo shunts are also double sterile wrapped.
The whole range is available from stock, so there's no delay when ordering. For more details, fill in the coupon.

Diagnosis of malignant hyperphenylalaninaemia

The occurrence of progressive cerebral degeneration in some patients with phenylketonuria (PKU) despite early and adequate dietary control of serum phenylalanine is now well established. The clinical syndrome was clearly described by Smith *et al.*[1] At a conference held in Lausanne, June 1977,[2] of groups of people who have written papers on the subject, it was agreed that malignant hyperphenylalaninaemia (MHPA) was the best term to describe such cases. Readers seeking additional documentation of the facts should refer to the report of that meeting.[3]

MHPA is present in between 1 and 3% of babies with positive results to Guthrie tests, including some babies with serum phenylalanine levels lower than would customarily be treated with diet.[4] All cases so far recognised suffer a deficiency of tetrahydrobiopterin (BH_4), the cofactor of phenylalanine hydroxylase, tyrosine hydroxylase, and tryptophan hydroxylase. Deficient production of the neurotransmitter products of tyrosine and tryptophan is regarded as the cause of the neurological effects[5] and the gratifying results reported in Lausanne of treatment with L-dopa and 5-hydroxytryptophan support this contention.[6] Two classes of basic defect have been found: deficiency of dihydropteridine reductase (DHPR) which is required for recycling BH_4[7] and defective synthesis of biopterin.[7,8,9] Paediatricians treating PKU are faced with the need to identify patients with MHPA in order to treat them effectively and also to allow confident dietary treatment for the remaining 97–99% of patients with PKU. Patients with MHPA can then be further classified by DHPR assay on cultured skin fibroblasts (or on liver biopsy), by phenylalanine hydroxylase assay (on liver biopsy), and in future by assay of specific enzymes concerned in BH_4 synthesis.

The time has now come to introduce systematic testing of all babies with persistently raised levels of serum phenylalanine by measuring the response to a single oral dose of BH_4 (2 mg/kg). This test should be performed as part of the initial work before diet is begun, and the serum phenylalanine level should be measured before and 6 hours after the dose.[4] MHPA is recognised by a fall of serum phenylalanine to normal levels; patients with classical PKU show no response.

The advantage of this method is that the result can be known immediately, before diet is started, and no other laboratory test is needed. Lack of pure BH_4 is the one problem at present, but if there were a demand from several clinics it could soon be made available. Several research laboratories are already synthesising BH_4 and the quantities needed are not great.

We showed the effect of intravenous BH_4 in a patient who was initially thought to have partial DHPR deficiency,[10] but was later found to have severe DHPR deficiency.[4] Comparable response in patients with deficient BH_4 synthesis was expected and has now been shown by Schaub *et al.* who also showed that oral administration was as effective as parenteral.[9]

Another useful approach to the recognition of MHPA is the study of urinary pteridines. The simplest method is to estimate dihydroxanthopterin (XH_2) in urine. DHPR deficiency causes excessive levels of XH_2 in the urine.[11] The levels overlap those found in patients with classical PKU before treatment, and clear distinction requires retesting after dietary control when levels are still high in DHPR deficiency but have fallen to normal in classical PKU. Urinary XH_2 should be abnormally low in patients with defects of BH_4 synthesis. One may expect to find some precursors of BH_4 in the urine in these cases. Doubtless high performance liquid chromatography of urine may give a diagnostic profile in such cases, but findings in DHPR deficiency can overlap those in classical PKU (before treatment). These approaches to diagnosis necessitate setting up new laboratory methods and there are likely to be delays in diagnosis because response to dietary treatment may be critical in some cases. Some of the chemicals measured are unstable in urine (in serum) and careful treatment of samples is necessary.

For all these reasons we feel convinced that the BH_4 load test will become established as the best method for identifying cases of MHPA promptly and efficiently. Many different approaches are then possible in evaluating these few patients with MHPA to reach a final diagnosis, but proof of the enzyme defect is likely to remain the final arbiter.

Neonatal form of dystrophia myotonica

Five cases in preterm babies and a review of earlier reports

R. G. PEARSE AND C. J. HÖWELER

Departments of Paediatrics and Neurology, Sophia Children's Hospital, and Academic Hospital, Erasmus University, Rotterdam

SUMMARY Five preterm babies with the neonatal form of dystrophia myotonica are reported. In addition to the generally accepted signs and symptoms of the disease, two other features were present in these patients; oedema was notable in all 5 babies and 4 had unexplained haematomas. It is suggested that premature birth may be a result of severe involvement and that prematurity further aggravates the symptoms.

The neonatal form of dystrophia myotonica is now recognised as a clinical entity which is quite different from the adult form of the disease (Vanier, 1960). The clinical picture is characteristic and consists of extreme hypotonia and generalised muscle atrophy, combined with polyhydramnios, insufficient respiratory activity after birth, joint deformities, and facial diplegia with a 'tent-shaped' mouth. The adult form of the disease, however, comprises myotonia and localised muscle atrophy with cataracts, frontal baldness, and testicular atrophy.

In a 7-month period, 5 preterm babies in whom the diagnosis of dystrophia myotonica could be made were admitted to our neonatal intensive care unit. We describe these babies, report two hitherto unstressed features of this disease, and review previous reports on the neonatal form of dystrophia myotonica.

Case reports

Case 1. A baby girl was delivered by caesarean section at another hospital at 30 weeks' gestation because of abruptio placentae. The pregnancy had been complicated by polyhydramnios. After delivery the baby made no spontaneous attempt to breathe and was ventilated by mask until the arrival of our neonatal transport team. She was intubated and given intermittent positive pressure ventilation (IPPV).

On admission she weighed 1840 g and was hypotonic (Fig. 1a) with a 'tented' upper lip (Fig. 1b),

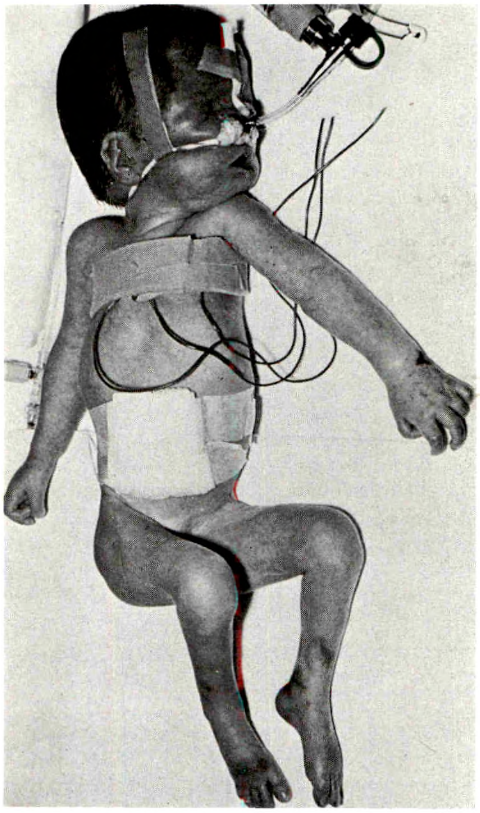

Fig. 1a *Characteristic posture of the premature infant with dystrophia myotonica. Hypotonia of the shoulder girdle can be seen with muscle atrophy in the legs and flexion contractures of the hips and talipes equinovarus.*

Sophia Children's Hospital and Neonatal Unit, Rotterdam, The Netherlands

C. J. HÖWELER, neurologist

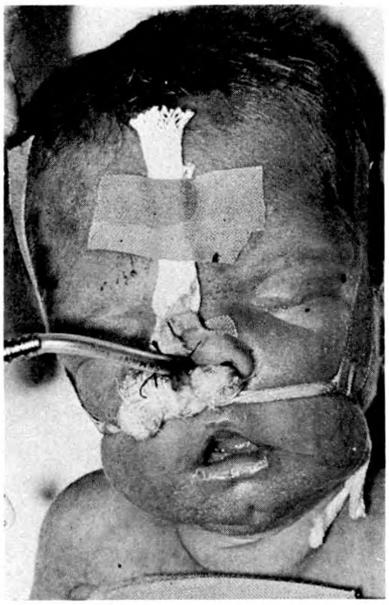

Fig. 1b *Typical facies of dystrophia myotonica in the newborn. The 'tent shaped' mouth and oedema are obvious. (See also Figs 3, 5, 7, and 9.)*

facial diplegia, and absent sucking and gag reflexes. She had unexplained haematomas of the labia minora (Fig. 1c), upper thighs, and arms, and pronounced oedema of the head and limbs. There were flexion contractures of the hips with talipes equinovarus, and the muscles of the arms and legs appeared atrophic (Fig. 1a). She lost 450 g (24% of birthweight) in the first 5 days in spite of intravenous feeding. This was thought to be due to the loss of oedema fluid. There was little change in her clinical condition and she died on day 19 without a diagnosis other than perinatal asphyxia. Necropsy examination gave no cause for her death. The diagnosis was made when the similarity was recognised between this baby and a baby admitted one month later (Case 2) in whom the diagnosis of dystrophia myotonica had been made. Subsequent examination of the mother of Case 1 confirmed the diagnosis.

The mother

A 33-year-old woman who had no spontaneous complaints. However on direct questioning she admitted to having had 'stiff hands' during this and previous pregnancies. On examination she had the classic findings of moderately severe dystrophia myotonica with a myopathic facies (Fig. 2), weakness of distal limb muscles, and myotonia of grip. She has two healthy children now aged 3 and 6 years. They have both been examined and have no symptoms or signs of dystrophia myotonica, but EMG and slit-lamp examination could not be performed. Her third pregnancy ended at 28 weeks with the delivery of a

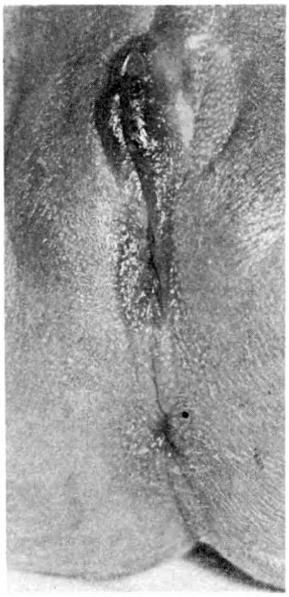

Fig. 1c *Haematoma of the labia minora.*

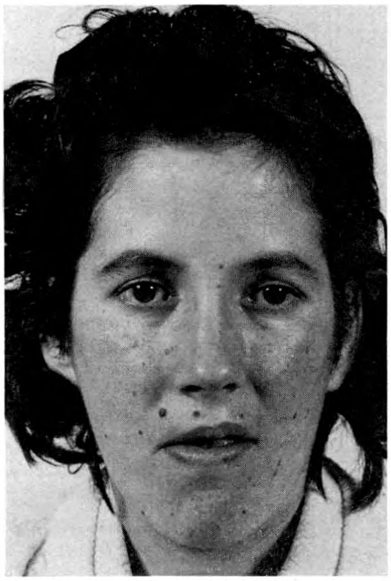

Fig. 2 *Mother of Case 1. Typical facies of dystrophia myotonica. Atrophy of the temporalis and masseter muscles can be seen, also ptosis and the typical smile of facial muscle weakness. (See also Figs 4, 6, 8, and 10.)*

1640 g baby who died soon after birth from respiratory insufficiency, supposedly secondary to prematurity. Four of the mother's five sisters have been shown to have dystrophia myotonica.

Case 2. A baby girl was born at home by spontaneous vaginal delivery at 36 weeks' gestation after a pregnancy complicated by polyhydramnios. She failed to breathe adequately after birth and was transferred to our hospital. On admission she weighed 2820 g and was cyanotic, hypotonic, hypothermic (34·4°C), and markedly oedematous. She had a 'tent-shaped' mouth (Fig. 3), facial diplegia, atrophy of limb muscles, and haematomas of the dorsal and palmar aspects of both hands for which no explanation could be found. Coagulation studies were normal. A differential diagnosis of cerebral haemorrhage or muscle disease was made. Lumbar puncture produced freely blood-stained CSF and CAT scan showed subarachnoid, interstitial, and intraventricular haemorrhage. A detailed family history taken at this time led to the diagnosis of dystrophia myotonica and subsequent examination of the mother confirmed this. During the first few days after birth the baby had episodes of apnoea and bradycardia of varying duration from which she spontaneously recovered. Thereafter the respiration improved and she began to move spontaneously. She still had difficulty in drinking and swallowing on discharge from hospital at age 7½ weeks when she weighed 3240 g. Her maximum weight loss in the first week was 480 g (17% of birthweight). She learned to sit unsupported and to roll at age 8 months. She is now 11 months and can stand with support, although she is unable to pull herself up to a sitting or standing position.

The mother

A 23-year-old woman who was unaware that she had dystrophia myotonica, although on questioning she had had myotonic symptoms in the hands since age 13. On examination she had mild but typical features of dystrophia myotonica (Fig. 4), including the characteristic cataracts and the EMG. Her father and brother were also found to have dystrophia myotonica. This was her first pregnancy.

Case 3. A baby girl was delivered by the breech at 33 weeks' gestation after a pregnancy complicated by polyhydramnios. She did not breathe spontaneously and during resuscitation attempts at introducing a nasogastric tube were unsuccessful, so that she was initially diagnosed as having oesophageal atresia. She was intubated and given IPPV, and then transferred to our hospital.

On admission she weighed 1350 g and was extremely hypotonic and oedematous. She made no spontaneous movements and was areflexic. She had generalised muscle atrophy with bilateral talipes equinovarus and flexion contractures of the hands and hips. There was a facial diplegia, a 'tent-shaped' mouth (Fig. 5), and haematomas over the limbs and upper thoracic and neck regions. Without IPPV she rapidly became cyanotic even in 100% O_2. There was no evidence of oesophageal atresia and the diagnosis of the neonatal form of dystrophia myotonica was made on the clinical findings, subsequently confirmed when we examined the mother. After 3 days

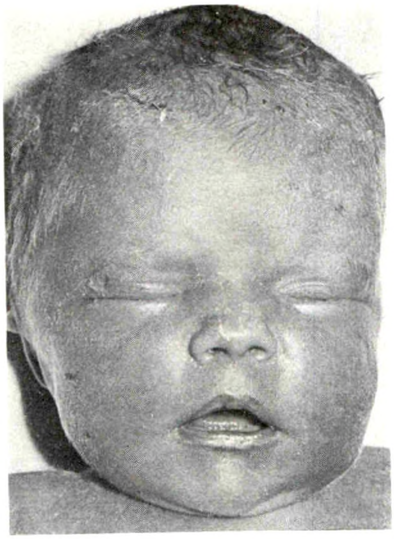

Fig. 3 *Case 2, showing same features as in Fig. 1b.*

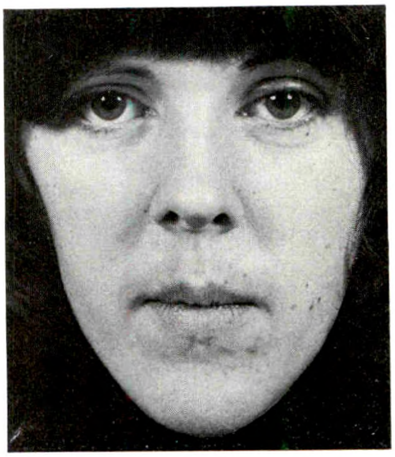

Fig. 4 *Mother of Case 2, showing same features as in Fig. 2.*

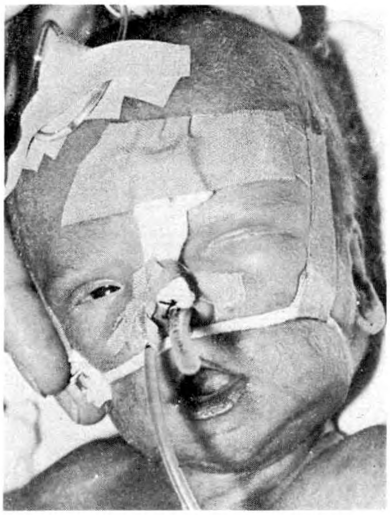

Fig. 5 *Case 3, showing same features as in Fig. 1b.*

on IPPV the baby died. At necropsy examination a subcapsular haematoma of the liver was found, plus the unexpected finding of agenesis of the corpus callosum. A coagulation screen done at age 24 hours was normal. Her maximum weight loss was 200 g (15% of birthweight).

The mother
A 21-year-old woman who had noticed myotonic symptoms since age 6 but, as she was familiar with them from her mother, uncle, and aunt, she had never reported them. She is mentally retarded and has an indistinct nasal speech. On examination she had typical myopathic facies (Fig. 6) and the findings of moderately severe dystrophia myotonica were confirmed by the EMG. This was her first pregnancy.

Case 4. A baby girl was born at another hospital at 34 weeks' gestation after a pregnancy complicated by polyhydramnios (9 litres) and premature contractions which had been treated with ritodrine chloride for one week. She was ventilated with a mask for 15 minutes but then was able to maintain a reasonable colour in 100% O_2. On admission to our hospital she weighed 2000 g and was hypotonic and oedematous. She had the typical facies of the neonatal form of dystrophia myotonica (Fig. 7), the muscles of her arms and legs were atrophic, and her feet were held in plantar flexion. There were haematomas of both legs and feet. Her respiration was inadequate and she was intubated and ventilated for 19 days. She developed congestive cardiac failure secondary to a patent ductus arteriosus which closed spontaneously. She had had difficulty with drinking but was discharged at 10 weeks weighing 3060 g. Her maximum weight loss in the first week was 445 g (22% of birthweight). She is now 7 months old but does not roll or sit. Her head control is poor but is improving.

The mother
A 26-year-old woman who was unaware of her muscle disease, although on direct questioning she

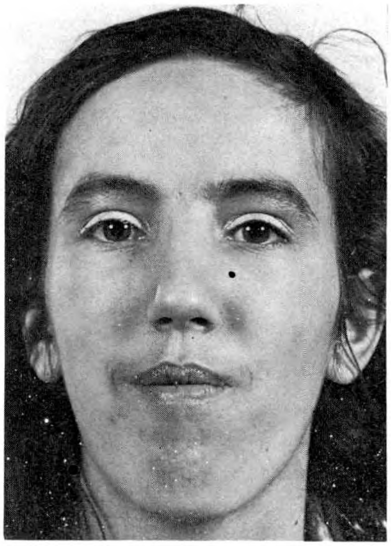

Fig. 6 *Mother of Case 3, showing same features as in Fig. 2.*

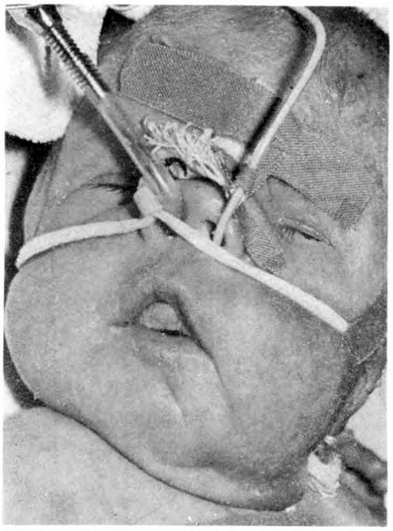

Fig. 7 *Case 4, showing same features as in Fig. 1b.*

had had myotonia of grip since age 18. On examination she had an obvious but mild degree of dystrophia myotonica (Fig. 8) and this was confirmed by the EMG. Her first pregnancy was complicated by polyhydramnios and ended at 33 weeks with the delivery of a baby who was hypotonic and did not breathe, attempts at resuscitation being unsuccessful. The mother's father has subsequently been shown to have a cataract typical of dystrophia myotonica although he has no muscle symptoms.

Case 5. A baby girl was delivered at 30 weeks' gestation at another hospital after a pregnancy complicated by polyhydramnios and a pyrexia of unknown origin just before delivery. The Apgar score was 3 at five minutes. She was intubated and transferred to our hospital on IPPV. On examination she was hypotonic and oedematous with the typical 'tent-shaped' mouth and facial diplegia (Fig. 9). Sucking and swallowing reflexes were absent and no tendon reflexes could be elicited. There were neither haematomas nor joint deformities but muscle atrophy was obvious. She was not weighed on admission but her weight was estimated to be about 2000 g. Her condition improved slowly but she required IPPV for 61 days. The clinical course was complicated by a patent ductus arteriosus which was closed surgically on day 44. She is now 6 months old and is still in hospital with feeding difficulties and recurrent pneumonia. She is hypotonic and is still being partially tube fed. She makes little or no contact.

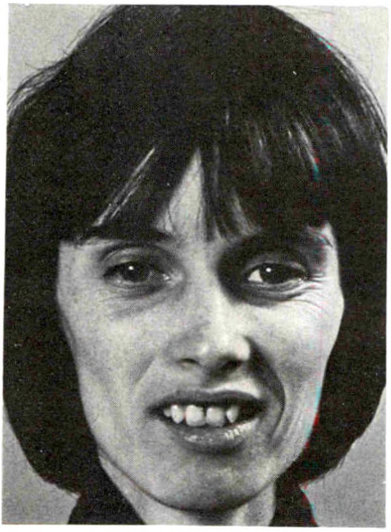

Fig. 8 *Mother of Case 4, showing same features as in Fig. 2.*

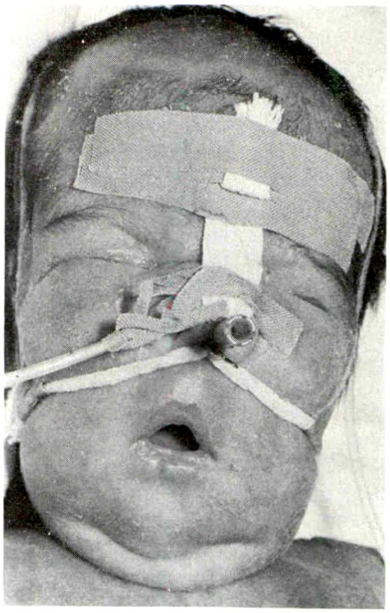

Fig. 9 *Case 5, showing same features as in Fig. 1b.*

The mother

A 37-year-old woman who was examined for dystrophia myotonica 4 months before the delivery because she is the sister of the mother of Case 1. She had had myotonic symptoms in the hands during this and the previous pregnancy although she had never complained of them. On examination she had obvious dystrophia myotonica of mild severity (Fig. 10) with cataracts and the typical EMG.

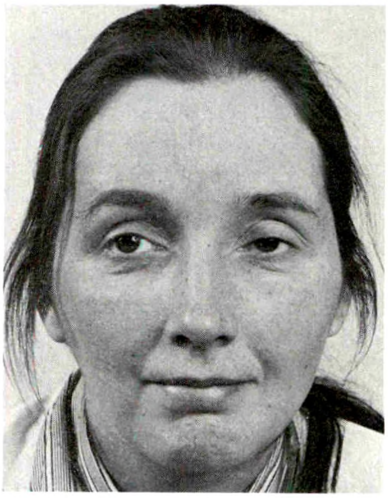

Fig. 10 *Mother of Case 5, showing same features as in Fig. 2.*

She has had two children now aged 11 and 13 years. They have no signs or symptoms of dystrophia myotonica and EMG and slit-lamp examination are normal in both. Her third pregnancy had been complicated by polyhydramnios and ended at 28 weeks with the delivery of a boy who failed to breathe, and died soon after birth.

Discussion

Dystrophia myotonica is a diagnosis which is easily missed in the newborn and is therefore probably not as rare as it would appear. This is supported by the high immediate postnatal mortality in families with dystrophia myotonica (Harper, 1975). The mother of Case 1 and her four affected sisters have between them had 21 babies of whom 8 have died soon after birth. In 5 of these there was documented polyhydramnios, suggesting that these babies died from dystrophia myotonica although the diagnosis was never made.

The individual symptoms of the disease as expressed in the newborn are nonspecific. However their occurrence in a particular combination makes recognition relatively easy. Some of these symptoms can be misleading. Severely affected babies often fail to establish adequate spontaneous respiration after birth. They are therefore diagnosed as having perinatal asphyxia, which may be considered adequate cause for the severe hypotonia seen. This receives apparent support when it is found that the baby also has difficulty with sucking and swallowing. However all these symptoms are an integral part of the neonatal form of dystrophia myotonica.

Harper (1975) described the characteristic features of the disease in newborn babies in his large retrospective study of 70 patients from 54 sibships. These are shown in the Table, together with the features described in 17 patients by other authors and in our series. There are obvious differences in the symptoms reported by Harper in this retrospective study and those reported in the series where the diagnosis was made in the neonatal period. All except one of the babies in Harper's series survived the neonatal period and only about half of them had respiratory difficulties. All the babies who were diagnosed in the neonatal period have had respiratory problems and half of them (11/22) have died.

The Table shows that the most commonly reported symptoms in the group diagnosed in the newborn period are respiratory insufficiency, hypotonia, joint deformities, and facial diplegia. Most of these babies have also had areflexia with muscle weakness and atrophy, and difficulty with sucking and swallowing. The inability to suck and swallow is probably the cause of the polyhydramnios (Dunn and Dierker, 1973) which has been found in all cases in which the quantity of amniotic fluid has been reported.

Table *Reported frequency of various symptoms and signs (where these are given) compared with the incidence in this series*

Symptoms and signs	*70 cases diagnosed retrospectively (Harper, 1975)*	*Reports* of 17 cases diagnosed in neonatal period*	*This study (5 cases)*	*Total cases diagnosed in neonatal period (22)*
Respiratory problems	33/70	17/17	5/5	22/22
IPPV necessary	—	10/17	4/5	14/22
Hypotonia	47/70	17/17	5/5	22/22
Joint deformities	33/70	17/17	3/5	20/22
Facial diplegia	61/70	13/14	5/5	18/19
Areflexia	—	8/10	5/5	13/15

Mortality	1/70	9/17	2/5	11/22
Transmission via mother	66/67	17/17	5/5	22/22
Delayed motor development	60/70	5/5	3/3	8/8

*L'Hirondel *et al.*, 1970; Bell and Smith, 1972; Messer *et al.*, 1973; Aicardi *et al.*, 1974; Bossen *et al.*, 1974; Simpson, 1975; Swift *et al.*, 1975; Sarnat *et al.*, 1976; van der Steeg *et al.*, 1977.

We found that oedema was characteristic in our patients (Figs 1b, 3, 5, 9). The average weight loss in the four babies in whom this was accurately known was 19·5% of birthweight, whereas in our unit it is less than 10% of birthweight for babies of a similar gestational age who receive similar treatment regimens. This weight loss was thought to be largely due to the loss of oedema fluid. Clinically the oedema was most noticeable on the limbs and head, while the trunk appeared relatively spared. The muscle artophy became more evident as the oedema disappeared. Oedema was also noted at birth in the patients reported by L'Hirondel *et al.* (1970) and Messer *et al.* (1973). An explanation for this oedema could be that secondary to reduced fetal movements there is reduction in lymphatic return from the periphery. The disappearance of the oedema in the first few days after birth may be related to the passive movements inherent in the intensive care of sick newborn babies.

A second notable feature in our cases was the existence of haematomas. In 4 of the 5 babies these were located in the skin, and one also had an intracerebral haemorrhage, and another baby a large subcapsular haematoma of the liver. Coagulation studies performed in 2 of the babies were normal. It can perhaps be postulated that these babies are unable to protect themselves against the trauma of delivery due to muscular weakness and hypotonia. However Stern *et al.* (1978) showed that abnormal capillary leakage occurs in the iris of adults with dystrophia myotonica during fluorescein angiography. Microvascular abnormality may thus be an important factor in the formation of haematomas in these babies but has yet to be studied.

The diagnosis of the neonatal form of dystrophia myotonica is essentially clinical. There are no laboratory tests which are diagnostic in the newborn period. Both muscle biopsy and EMG give only supportive evidence and necropsy examination does not provide the diagnosis. If the diagnosis is suspected, it can be confirmed by examining the mother. Although the disease is transmitted as an autosomal dominant, the neonatal form always appears to be transmitted via the mother (Harper and Dyken, 1972). An initially negative family history does not exclude the diagnosis because the mother may be so mildly affected that she may be unaware that she has the disease. The signs which should be particularly sought are the characteristic facies (Figs 2, 4, 6, 8, 10) with facial weakness, hollow temples, myotonia of grip, and percussion myotonia of the thenar eminence. Inability to bury the lower eyelashes when closing the eyes tightly is a useful early sign of the disease in adults. Slit-lamp examination and EMG may be performed to confirm the diagnosis in the mother. Only one of the mothers in our series was known to have dystrophia myotonica at the time of delivery.

The differential diagnosis of the congenital form of dystrophia myotonica includes all the causes of the 'floppy infant' (Dubowitz, 1969). Thus cerebral depression from anoxia, trauma or drugs, spinal cord injury, neonatal myasthenia gravis, Werdnig-Hoffmann's disease, and other congenital myopathies should be considered.

Unlike the reported cases, all the babies in our series were preterm. Sarnat and Silbert (1976) suggested that the symptoms in the neonatal period are due to relative immaturity of muscle tissue. Thus more severe symptoms could be expected in the preterm baby. However, there is probably a spectrum of severity in the intrauterine involvement of babies with dystrophia myotonica, ranging from the fetus who is aborted early in the pregnancy, through the baby who is born preterm and dies soon after birth, to the term and mildly affected baby who survives. Thus the baby born preterm may be both more severely affected and have had less time in which maturation of muscle tissue could take place. As would be expected in severely affected babies, polyhydramnios was present in all of our cases, and was probably one of the factors responsible for the premature delivery. It may be possible to delay delivery with uterine relaxants and by the repeated removal of excess amniotic fluid. This may moderate some of the life-threatening symptoms of the neonatal period by allowing the muscles more time to mature.

Harper and Dyken (1972) suggested that the neonatal form of dystrophia myotonica may be caused by an abnormal factor in the mother's serum which crosses the placenta but only affects babies carrying the abnormal gene. If this is so, then it is clear that it operates from early in pregnancy as our most premature affected infant was of 30 weeks' gestation and she already had joint contractures suggesting that the factor, if present, had been operative for some time.

Difficult ethical problems arise once the diagnosis has been made. If babies with dystrophia myotonica survive the first few weeks then there is a gradual improvement, at first in respiration, followed by improvement in swallowing, and eventually in the hypotonia. Although their development is slower than normal, most of them learn to walk and speak (Harper, 1975). However the long-term prognosis is poor and there is little hope of an independent life due to the combination of mental retardation and muscle weakness. Dyken and Harper (1973) found an average IQ of 56 in 14 patients who had had respiratory symptoms in the neonatal period.

Because the baby fails to breathe adequately immediately after birth, and usually the mother is not known to have dystrophia myotonica, the diagnosis is made when the baby is already being ventilated. We found it difficult to decide whether, and to what extent, we should continue treatment. The prognosis for both mental and physical handicap was discussed with the parents, but in each case they requested that every measure should be taken to keep the baby alive. The shock of hearing that both mother and baby have a serious disease must make a well-judged decision at such an emotional time extremely difficult for the parents.

Antenatal diagnosis could alleviate some of these problems. The gene for dystrophia myotonica is linked to the gene for secretor status and the latter can be determined in saliva and amniotic fluid. However this linkage is only helpful in antenatal diagnosis in about 15% of couples (Schrott *et al.*, 1973).

Until a better technique for antenatal diagnosis becomes available, the only reasonable approach would seem to be to attempt to identify all affected members of families with dystrophia myotonica and to offer genetic advice if appropriate. Recognition of the neonatal form of dystrophia myotonica can lead to the identification of such families and to more timely genetic counselling.

We thank the doctors and nurses involved in the treatment of these patients, the parents and relatives of the babies who co-operated in the family studies, the audio-visual departments of Sophia Children's Hospital and Dijkzigt for the photographs, and Mrs M. de Bruijne for secretarial help.

A year's experience of the rotavirus syndrome and its association with respiratory illness

HELEN M. LEWIS, J. V. PARRY, HEATHER A. DAVIES, RUTH P. PARRY,
ANGELA MOTT, R. R. DOURMASHKIN, P. J. SANDERSON, D. A. J. TYRRELL,
AND H. B. VALMAN

SUMMARY In a hospital study rotavirus was identified in 51% of 152 children with diarrhoea. These patients showed a clinical pattern that was distinct from patients in whom the diarrhoea was associated with bacteria, other viruses, or no pathogens. A respiratory illness was described in 66% of rotavirus patients and usually preceded the gastrointestinal symptoms. Vomiting lasted between one and 3 days and was curtailed by substituting the normal diet with clear fluids. Watery diarrhoea continued for 4 or 5 days, even when rehydration was by the intravenous rather than the oral route. Prolonged diarrhoea was rare. Most children infected with rotavirus were under 2 years of age, but dehydration was most severe in infants aged between 12 and 18 months. A clinician can thus recognise the rotavirus syndrome and expect spontaneous recovery if adequate rehydration is maintained for a critical few days.

The clinical features of patients admitted to hospital with gastroenteritis were studied in north-west London between 1968 and 1970 (Sinha and Tyrrell, 1973). The results showed that there was a distinct nonbacterial, winter epidemic disease which mainly affected children under 2 years and was often associated with symptoms and signs in the respiratory tract. An 'infantile gastroenteritis virus' was predicted and this was soon proved correct. Reports have universally shown that rotavirus particles can be seen in the stools of 15 to 90% of infants with diarrhoea but are absent from the stools of most healthy children. The highest isolation rates have been in temperate climates, particularly in the winter months (Bishop *et al.*, 1974; Davidson *et al.*, 1975; Kapikian *et al.*, 1976; Dupont *et al.*, 1977; Konno *et al.*, 1977; Schoub *et al.*, 1977; Walker-Smith, 1978).

Most observations of the clinical features of rotavirus infection indicate that vomiting is common (Shepherd *et al.*, 1975; Rodriguez *et al.*, 1977; Tallet *et al.*, 1977) and dehydration can be severe (Rodriguez *et al.*, 1977; Tallet *et al.*, 1977). Concurrent respiratory symptoms have been noted in retrospective analysis but have not proved significantly more frequent than in cases where diarrhoea is not associated with rotavirus (Carr *et al.*, 1976; *British Medical Journal*, 1977a; Rodriguez *et al.*, 1977; Tallet *et al.*, 1977). Because of possible omission of relatively mild respiratory symptoms in a predominantly gastrointestinal illness these studies do not show the true incidence or importance of respiratory tract involvement.

The patients in this prospective study lived in the same geographical area as those reported in 1968–70 (Sinha and Tyrrell, 1973). The aims were to define the clinical features of rotavirus infection and to explore the association between respiratory illness and pathogen in infantile gastroenteritis.

Patients and methods

The patients were children admitted to the paediatric or infectious diseases unit of Northwick Park Hospital during a complete year (1977); they had

Northwick Park Hospital and Clinical Research Centre, Harrow
HELEN M. LEWIS, senior paediatric registrar

Central Public Health Laboratory, London
JOHN V. PARRY, senior medical laboratory scientific officer

passed frequent loose stools for at least 24 hours at some stage of their illness and required replacement of the normal diet with clear fluids. Nearly all children were examined by the same clinician within 24 hours of admission and each day thereafter, and the findings were recorded on a standard form. Stools and throat swabs were collected once from each child as early in the illness as possible. Stools were studied by electron microscopical examination for rotavirus. The stools and throat swabs were cultured for viruses and for pathogenic bacteria. From some children who had signs of respiratory illness, nasopharyngeal secretions were aspirated and material from a plain throat swab was smeared on to a glass slide. These were stored, and 10 specimens were later examined by electron microscopy because virus particles were seen in the corresponding faecal specimens.

Stools for virology were sent immediately to the laboratory or stored at −70°C. A 10% suspension of stool was prepared in nutrient broth containing penicillin, streptomycin, and amphotericin B. The suspension was centrifuged at 2500 *g* for 10 minutes, then the supernatant was centrifuged at 10 000 *g* for 30 minutes at 4°C to remove bacteria. This supernatant was used for electron microscopical examination and for virus isolation tests. For electron microscopy 2 ml of faecal extracts were ultracentrifuged at 100 000 *g* for one hour at 4°C, and the deposit was negatively stained with potassium phosphotungstate using a technique described elsewhere (Flewett *et al.*, 1974). Grids were examined in a Philips EM 300 at a viewing magnification of 28 000.

For viral culture, 0·2 ml of stool suspension was inoculated into 2 tubes of each of 3 types of tissue cultures: human embryonic lung fibroblasts (MRC 5), Ohio HeLa cells, and secondary monkey kidney cells. Inoculated tissue cultures and uninoculated controls were incubated in roller drums at 33°C.

Throat swabs for virus isolation were taken on sterile plain cotton swabs and broken into virus transport medium (nutrient broth with antibiotics). If possible, throat swabs were kept at 4°C until inoculation. Within 2 hours 0·2 ml of the fluid was inoculated into 2 tubes of each of the 3 tissue cultures.

Viruses from both stools and throat swabs were detected by their cytopathic effects. Haemadsorption tests were performed on monkey kidney cells which were inoculated with respiratory specimens. Some adenovirus and enterovirus isolates have not been serotyped. Cultures were incubated for 4 weeks before they were discarded as negative.

Nasopharyngeal secretions were aspirated after injection of 2 ml normal saline into each nostril. This material was ultracentrifuged at 100 000 *g* for one hour. The resulting pellets were fixed in glutaraldehyde and osmium tetroxide buffered solutions, embedded in Spurr resin and sectioned. Sections were stained with uranyl acetate and lead, and examined for virus particles by electron microscopy. Both the nasopharyngeal secretions and the smeared slides from throat swabs were examined by negative staining (Flewett *et al.*, 1974).

For bacteriology fresh stool specimens were plated on to deoxycholate agar and MacConkey's medium, and inoculated into selenite broth. Enteropathogenic *Escherichia coli* were identified using antisera (Central Public Health Laboratory, Colindale) to 15 recognised enteropathogenic types. From April 1977 a selective medium was used to isolate campylobacter species (Skirrow, 1977). Microscopical examination of stool specimens for parasites was performed if there had been diarrhoea for more than 10 days or if the child had recently returned from abroad.

Bacterial throat swabs were taken on sterile serum-coated wool buds and transported in Stewart's medium. They were cultured on blood and chocolate agar. Colonies were identified by standard techniques and all streptococci were grouped serologically.

The completed clinical and microbiological data were punched on to computer cards. Tables and significance tests were produced by computer analysis (Nelder, 1974).

Results

A total of 150 children were studied and 8 were rejected because they did not pass any stools after admission. Two children were admitted twice, but as both were asymptomatic between admissions each illness was considered as a separate episode. Thus 152 episodes of diarrhoea were investigated and these were divided into 5 groups according to the pathogens identified in the faeces (Table 1).

The largest was group 1 containing 74 patients from whom rotavirus was detected, although on tissue culture, 6 of these also showed an adenovirus and 3 an enterovirus.

Table 1 *Results of testing faeces*

Group	*Stool pathogens*	*Patients n=152*	
		No.	*(%)*
1	Rotavirus	74	(49)
2	Pathogenic bacteria	23	(15)
3	Other viruses	26	(17)
4	No pathogens	26	(17)
5	Rotavirus and pathogenic bacteria	3	(2)

Group 2 contained 23 patients with pathogenic bacteria: salmonella 9, shigella 8, enteropathogenic *E. coli* 1, and campylobacter species 5. Of these, one child had *Giardia* on light microscopy and 2 showed an adenovirus, detected by tissue culture.

Group 3 contained 26 patients from whom viruses other than rotavirus were the only pathogens identified. The results of tissue culture were: adenovirus 9, enterovirus 9. Electron microscopical examination showed adenovirus 3, enterovirus 3, astrovirus 1, coronavirus 1, and calicivirus 2. On only 2 occasions was a virus of the same type (both adenoviruses) found by tissue culture as well as by electron microscopy.

In the stools of patients in group 4 no pathogens were found. Group 5 contained 3 patients who showed both rotavirus and pathogenic bacteria—*Salmonella berkeley*, *Salmonella typhimurium*, and *E. coli* O125.

Altogether 125 throat swabs were taken for virology and results of 17 (14%) were positive; they yielded adenovirus 4, enterovirus 2, cytomegalovirus 5, herpes simplex 1, respiratory syncytial virus 1, rhinovirus 3, and parainfluenza 1. 135 throat swabs were taken for bacteriology and results of 22 (16%) were positive; they comprised streptococci group A 3, streptococci group B 5, streptococci group C 1, *Streptococcus pneumoniae* 4, *S. faecalis* 1, and haemophilus species 8. In 5 patients a virus of the same group was isolated from both stool and throat (adenovirus 4, and enterovirus 1). The throat swabs and nasopharyngeal secretions examined by electron microscopy belonged to 9 patients with rotavirus and one with an adenovirus seen on stool electron microscopy. A papilloma virus was found in material from the throat swab of one patient who had rotavirus in the stool but no virus particles were identified in any other respiratory specimen.

The clinical features of the 4 main groups of stools were compared but the 3 patients in group 5 were excluded. The results for all 4 groups were tested for nonuniformity by the χ^2 test and reported as significant when $P<0\cdot05$. Clinical features were recorded before any microbiological results were received. Bacteriological reports were obtained within 3 days, but virology and electron microscopical examination were not completed until after the patient had been discharged from hospital and so could not bias the clinical observations.

At least one dose of an antibiotic was known to have been taken by 46 children before admission. These children included a few with bacterial infections, but the differences between the groups were not significant (35·5%, 17%, 27%, and 35% respectively, for groups 1 to 4).

Patients.

Sex

There were 88 (59%) boys and 62 (41%) girls. Sex ratios in the 4 stool groups were 58%, 65%, 58%, and 62% boys in groups 1 to 4 respectively, and these were not significantly different.

Age

Fig. 1 shows the ages of the patients. The youngest was 8 days old and the oldest 13 years. The 4 groups showed different patterns ($\chi^2 = 42\cdot9$, $P = 0\cdot008$). Rotavirus was most common in babies of between 6 and 18 months, and other viruses or no pathogens below 6 months, but bacterial pathogens occurred in fairly equal numbers at each age. 15 (10%) patients were less than 3 months of age and rotavirus was identified from only 2 of these babies.

Month of admission

Fig. 2 shows the seasonal pattern of admissions. Rotavirus infection occurred mainly in the first 6 months of the year with a peak in January and February. The other groups showed no pronounced seasonal pattern.

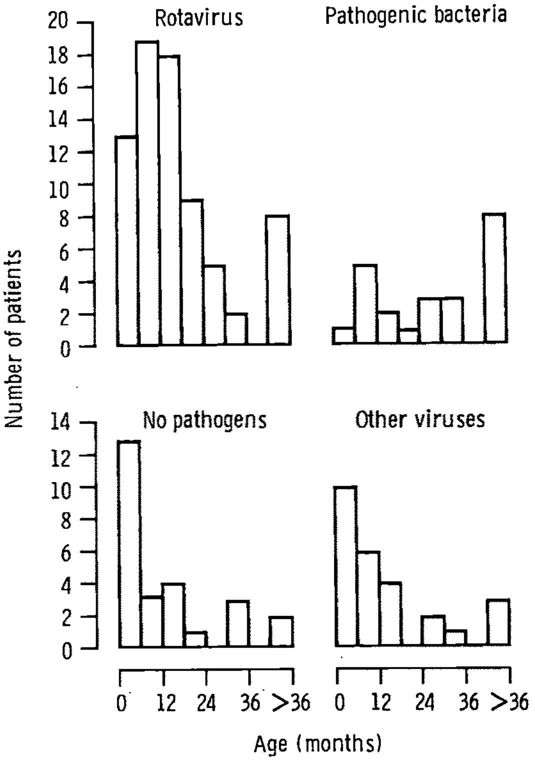

Fig. 1 *Age distribution of the patients.*

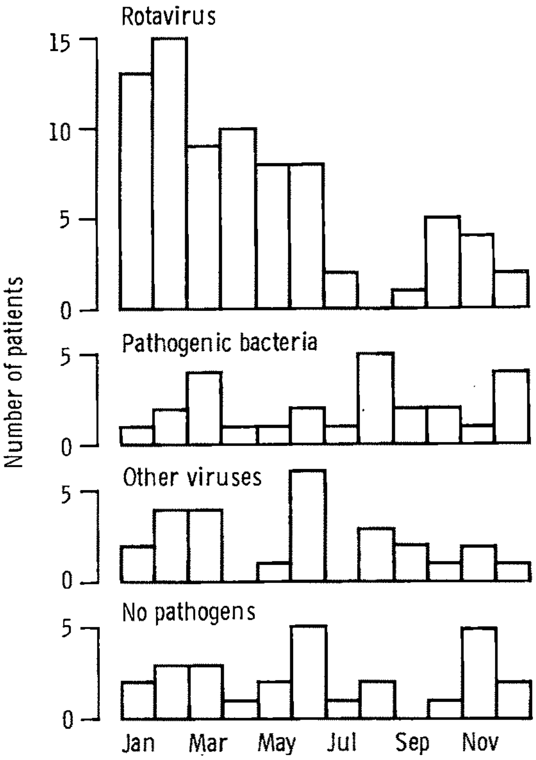

Fig. 2 *Monthly incidence of gastroenteritis.*

Clinical features.

Vomiting

69 (93%) out of 74 patients excreting rotavirus vomited for at least one day, compared with 10 (43%) out of 23, 14 (54%) out of 26, and 20 (77%) out of 26 in groups 2 to 4 respectively ($\chi^2 = 32{\cdot}6$, $P<0{\cdot}001$). Fig. 3 shows the number of patients who vomited for at least one, for at least 2, etc. days before and after admission, but not necessarily on consecutive days. In group 1 the median duration of vomiting was one to 2 days before admission, after which most patients either did not vomit at all or had stopped within 24 hours. A similar pattern was observed in the other groups. In groups 3 and 4 proportionately fewer patients vomited but they tended to vomit for longer ($\chi^2 = 42{\cdot}60$, $P = 0{\cdot}009$).

Diarrhoea

Patients were only included in the study if they had diarrhoea for at least one day, and Fig. 4 shows the number of days on which this was reported before and after admission. In the rotavirus group diarrhoea usually persisted for 2 to 3 days after admission, and the median total duration of diarrhoea was 4 to 5 days, with a mean of 5. In the other groups it lasted significantly longer, means of 7·3, 9·1, and 8·5 days in groups 2 to 4 respectively ($\chi^2 = 51{\cdot}5$, $P = 0{\cdot}003$). Blood in the stools was recorded only in the group with bacterial infection (10 (38%) out of 26) and in one patient in whom no pathogens were found.

Severity of dehydration

Intravenous fluids were administered to children with more than 5% dehydration clinically, and also to those who continued to vomit after they were given oral glucose electrolyte mixture. The use of IV fluids was taken as an index of the severity of dehydration. More rotavirus patients had IV fluids (39%), compared with 13%, 12%, and 23% in groups 2 to 4 respectively ($\chi^2 = 11$, $P = 0{\cdot}01$).

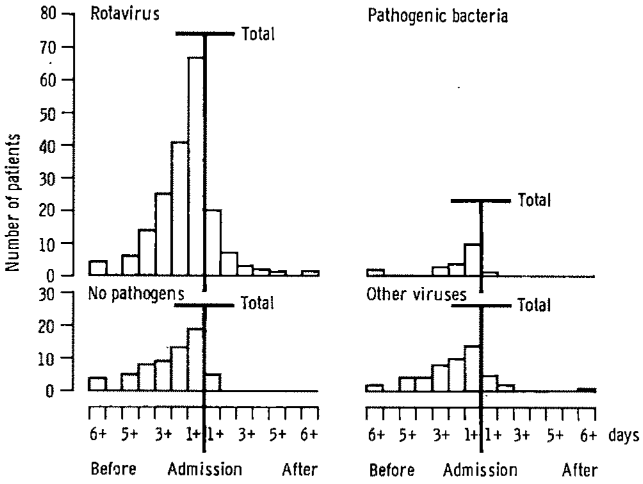

Fig. 3 *Number of days on which vomiting was recorded.*

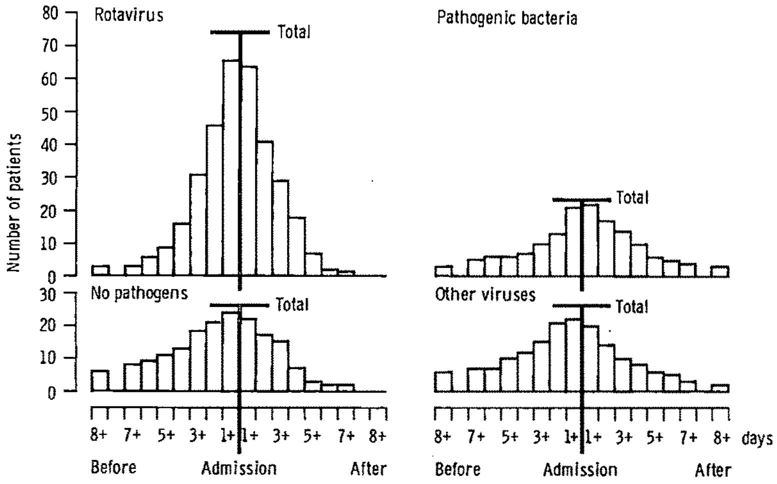

Fig. 4 *Number of days on which diarrhoea was recorded.*

Fig. 5 shows the proportion of patients of various ages that received IV fluids in the rotavirus group compared with the others. In the rotavirus group there was a highly significant peak at 12 to 18 months, when 75 % of patients excreting rotavirus were given IV fluids and 3 of them had hypernatraemic dehydration (plasma sodium >155 mmol/l).

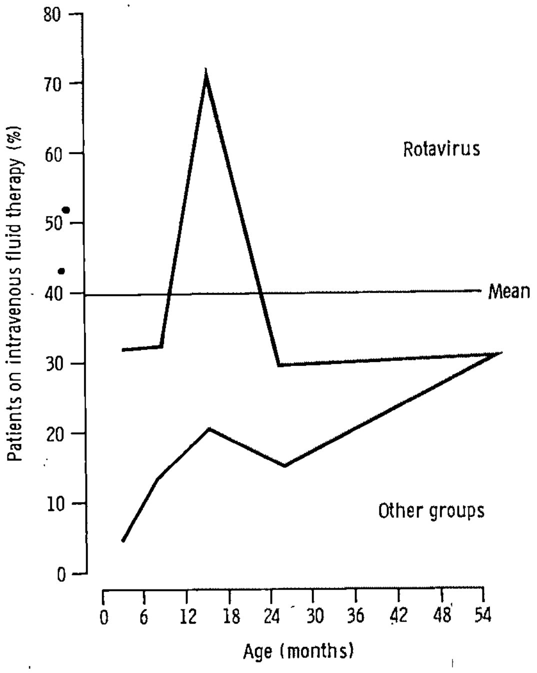

Fig. 5 *Relationship between age and treatment with intravenous fluids.*

Respiratory infection

Observations showing that the respiratory tract was affected are summarised in Table 2. A patient was classified as having respiratory involvement from all evidence of respiratory illness, either by the history or by clinical observations; on this basis 66 % of rotavirus patients had respiratory illness compared with 26 to 38 % of other groups ($\chi^2 = 16$, $P = 0{\cdot}01$).

There was no correlation between a positive bacterial or viral throat swab and respiratory illness ($\chi^2 = 0{\cdot}07$, $P = 0{\cdot}03$), nor with the patient being in the rotavirus or any other group ($\chi^2 = 4{\cdot}1$, $P = 0{\cdot}25$).

Incidence of fever

62 % of rotavirus patients had a maximum recorded rectal temperature of 37·5°C or more compared with 57 %, 58 %, and 58 % in the other groups, but the differences were not significant ($P = 0{\cdot}05$).

Discussion.

This study shows that diarrhoea attributed to rotavirus is more often associated with a respiratory illness than is diarrhoea attributed to other pathogens. A history of a preceding cough, nasal discharge, or otitis media was the outstanding clinical difference between rotavirus patients and the others. Likewise, after admission to hospital a red throat or red, bulging tympanic membranes were seen more often in the rotavirus patients than in others. Viruses and bacteria were isolated with equal frequency from the throat swabs of patients with respiratory symptoms as from those with no such symptoms. This suggests that the rotavirus, rather than any

Table 2 *Evidence of respiratory infection*

Clinical features	*Group 1* (*rotavirus*)	*Group 2* (*bacteria*)	*Group 3* (*other viruses*)	*Group 4* (*no pathogens*)	*Significance*

other agent, was responsible for the respiratory features.

However, no rotavirus particles were found by electron microscopical examination of nasopharyngeal secretions and throat swabs from 9 children with rotavirus in their stools and signs of an upper respiratory infection. The rotavirus may have been present in the upper respiratory tract at an earlier stage in the illness or in concentrations too low to be detected by electron microscopy (Davidson *et al.*, 1975).

Although this study showed a seasonal peak in winter (Fig. 2), rotavirus was isolated throughout the year. In temperate climates there may be endemic infection with superimposed winter epidemics; in tropical countries rotavirus is isolated particularly in the rainy season and is more common in areas of high humidity (T. H. Flewett, 1978, unpublished observation). Epidemics could be related to different serotypes (Fonteyne *et al.*, 1978; Zissis and Lambert, 1978) and transmitted by droplet infection via the respiratory tract, while endemic infection may be transmitted by the faeco-oral route.

Rotavirus illness was usually accompanied by vomiting which preceded the diarrhoea (Fig. 3). After admission to hospital, vomiting stopped but diarrhoea persisted for 2 or 3 days (Fig. 4). A few patients became rapidly dehydrated as a result of passing profuse watery stools even when they were receiving IV fluids only. The observation that diarrhoea attributed to rotavirus lasted for up to 5 days, despite admission to hospital, suggests that rational treatment can be planned from a clinical recognition of the syndrome. In the past, schemes for the management of dehydration associated with gastroenteritis have been constructed mainly for infants under one year of age infected with enteropathogenic *E. coli*. An electrolyte mixture is customarily given orally or intravenously for 24 hours; then the child is gradually weaned to full strength milk over 5 days. For the rotavirus syndrome it may be preferable to give an electrolyte mixture for 2 or 3 days, and then regrade rapidly if dilute milk or a light diet is tolerated. Our children were usually on a normal diet after 5 days and this regimen rarely produced prolonged diarrhoea.

The most severely dehydrated children excreting rotavirus were aged between 12 and 18 months, only 2% of the whole series had hypernatraemic dehydration and there was only one patient with persistent disaccharide intolerance. Recent surveys from Hackney (London) and Newcastle upon Tyne show a decline in the duration and severity of infantile gastroenteritis (*British Medical Journal*, 1977b; Pullan *et al.*, 1977; Tripp *et al.*, 1977) but severe dehydration and prolonged diarrhoea were still common in the very young babies. In the present study only 10% of the children were under 3 months, and from the younger babies, other viruses or no pathogens were found in the stools more often than rotavirus. A comparatively high incidence of early breast feeding in the area served by this hospital (Coles *et al.*, 1978) may account for the rarity of both recognised enteropathogenic serotypes of *E. coli* and early infection with rotavirus (Bullen, 1977; Thouless *et al.*, 1977). The practice of feeding low solute milks for the first months of life may have helped to prevent severe dehydration and hypernatraemia.

Comparison between this study and others in the UK should take into consideration the social and cultural background of the indigenous population. Neither social class nor ethnic group was recorded on the proforma, but in retrospect, 66 (44% of the total) patients were children of immigrants to this country who were predominantly Asian refugees from East Africa. Many lived in over-crowded accommodation and, in some cases, bacterial infection was imported from overseas either by the child himself or by another member of the household.

Rotavirus (group 1) and bacterial (group 2) patients should be compared with caution with groups 3 and 4 in which the nature of the pathogen is not established. No pathogens were found in 17% of children but there may have been unidentified viruses, or enteropathogenic strains of *E. coli* which were not detected by the serological methods used. Other studies show that complement-fixation tests on paired sera can detect rotavirus in patients whose stools were negative by electron microscopical examination (Kapikian *et al.*, 1975; Gomez-Barreto *et al.*, 1976; Gust *et al.*, 1977); as such examination is usually negative by 6 days after the onset of diarrhoea, rotavirus may have been missed in 8 cases with a longer history.

Except in the neonatal period, rotavirus is rarely identified in the stools of asymptomatic children (Albrey and Murphy, 1976; Totterdell *et al.*, 1976; Gust *et al.*, 1977; Murphy *et al.*, 1977) but the same is not true of other stool viruses (Stott *et al.*, 1967; Flewett *et al.*, 1974; Flewett, 1976; Madeley *et al.*, 1977). This study did not include a group with no diarrhoea but it was conducted concurrently with a study of viruses isolated from children of the same age who were admitted with febrile convulsions (Lewis *et al.*, 1979). There was no significant difference in the rate of isolation of enteroviruses or adenoviruses from the stools of these two groups of patients, but rotavirus was found in only 2 (3%) out of 62 children with febrile convulsions and each had a febrile illness followed by diarrhoea. Two children in the gastroenteritis study had febrile convulsions. One had an adenovirus isolated from the throat and stool and the other was infected with *Shigella sonnei*.

Despite the limitations of the comparative analysis, this survey has shown distinctive clinical features in patients excreting rotavirus; in particular, diarrhoea was not usually the first symptom. General practitioners and paediatricians should therefore consider rotavirus in the differential diagnosis of vomiting, unexplained dehydration, pharyngitis, acute otitis media, or an unexplained fever, particularly in children from 6 to 24 months of age and in winter.

We thank the technicians in the Department of Microbiology, Dr C. C. Spicer and Dr E. C. Coles for statistical advice, Mrs Spurgeon and the Department of Medical Illustration for preparing the figures, and Dr Hillas Smith and Dr M. Liberman for allowing study of their patients.

Plasma 17OH-progesterone concentrations in newborn infants

I. A. HUGHES, D. RIAD-FAHMY, AND K. GRIFFITHS

Tenovus Institute and Department of Child Health, Welsh National School of Medicine, Cardiff

SUMMARY Plasma concentrations of 17OH-progesterone were determined in 60 normal newborn infants aged between 3 and 36 hours. Mean levels decreased rapidly during this time after removal of the placental contribution of this steroid. A further 70 normal infants, studied between ages 2 and 7 days, showed a mean plasma 17OH-progesterone concentration of 3·5 nmol/l (1·2 ng/ml). By comparison, plasma concentrations in untreated infants with congenital adrenal hyperplasia were markedly raised. At 36 hours of age, there was an obvious difference between plasma levels of this steroid in normal and affected infants. Determination of plasma 17OH-progesterone concentrations are valuable in the evaluation of disorders of sexual differentiation and electrolyte balance in newborn infants, provided due care is given to the timing of sample collections.

It is now well established that plasma concentrations of 17OH-progesterone are markedly raised in untreated congenital adrenal hyperplasia (CAH) due to C-21 hydroxylase enzyme deficiency (Barnes and Atherden, 1972; Youssefnejadian and David, 1975; Hughes and Winter, 1976). Consequently, requests for measuring this steroid in plasma collected from newborn infants with ambiguous genitalia are increasing in frequency. The Supraregional Assay Service Laboratory at the Tenovus Institute receives numerous blood samples each week for determination of plasma 17OH-progesterone concentrations. Many of these samples have been collected within the first 48 hours of life at a time when, because of placental 17OH-progesterone production (Tulchinsky and Simmer, 1972), plasma concentrations are raised in normal newborn infants. There is a limited amount of information on plasma concentrations of 17OH-progesterone during early life and on the time taken for levels to decrease to values observed in later infancy and childhood. This report gives data on plasma 17OH-progesterone concentrations in mixed cord blood and in a group of normal newborn infants studied during early postnatal life. The results are compared with those found in untreated newborn infants with CAH.

Patients and methods

Mixed cord blood samples were obtained from 19 babies (10 boys and 9 girls) immediately after cord clamping. Their gestational ages ranged from 37 to 41 weeks. Capillary blood was collected by heel prick from 60 infants who were products of uneventful term pregnancies. There were 32 boys and 28 girls, whose postnatal ages ranged from 3 to 36 hours at the time of sample collection. Maternal consent for the study was obtained in each case. Plasma samples collected from 70 infants up to 7 days' postnatal age and sent to this laboratory were also available for analysis. Several infants with CAH due to C-21 hydroxylase deficiency were studied during the first week of life before starting steroid replacement therapy. Their plasma 17OH-progesterone concentrations were compared with those determined in normal infants.

Plasma 17OH-progesterone was measured by radioimmunoassay (RIA) using an antiserum kindly donated by Dr D. L. Loriaux, NIH, Bethesda. The sensitivity of the assay was 4 pg/tube using 200 μl plasma. Apart from 11-deoxycortisol (3·3%) and 21-deoxycortisol (1·6%), the cross-reactivity of the 17OH-progesterone antiserum with numerous other steroids, including progesterone, was less than 0·1% The intra-assay coefficient of variation was ± 6·3%; the inter-assay coefficient of variation was ± 7·5% (high pool) and 11·9% (low pool). All RIA data processing was performed using the method of

K. GRIFFITHS, director, Tenovus Institute

Rodbard and Hutt (1974) and quality controlled by the method of Kemp *et al.* (1978). The mathematical relationship between plasma concentration (Y) and the age of the newborn infant (t) was reasonably described by a power function of the form $Y = At^B$ within the time-span of sampling. The index of determination was 0·72 and values of A and B determined by least squares analysis of data contained in Fig. 1, using a linear transformation of this equation, were 151 and −0·906 respectively.

Results

Mean values for plasma 17OH-progesterone concentrations in mixed cord blood were 203 ± 37·8 SD nmol/l (69 ± 12·9 ng/ml) for boys and 184 ± 34·5 SD nmol/l (62·6 ± 11·7 ng/ml) for girls. There was no significant sex difference. The individual plasma 17OH-progesterone concentrations for 60 newborn infants in relation to postnatal age are shown in Fig. 1. The line represents the mean plasma 17OH-progesterone concentration for the whole group of infants, there being no significant difference between mean concentrations in boys and girls. The mean plasma 17OH-progesterone concentration fell rapidly after birth, from 45 nmol/l (16 ng/ml) at 12 hours, to 8·5 nmol/l (2·9 ng/ml) at 24 hours, and 6 nmol/l (2 ng/ml) by 36 hours of age. This represents a 32-fold decrease from the mean cord plasma 17OH-progesterone concentration. The pattern of plasma 17OH-progesterone concentrations in normal infants during the first week of life is shown in Fig. 2. Mean levels reached a nadir of about 3·5 nmol/l (1·2 ng/ml) by 7 days of age. This contrasts with plasma 17OH-progesterone concentrations in untreated CAH infants during the first 7 days of life. At 12 hours' postnatal age, there was a wide difference between plasma 17OH-progesterone concentrations in normal and CAH infants. By the 2nd day there was a 40-fold

difference in mean plasma 17OH-progesterone concentrations.

Discussion

This study confirms previous reports of a raised cord plasma 17OH-progesterone concentration reflecting placental production of this steroid (Jenner *et al.*, 1970; Lippe *et al.*, 1974; Winter *et al.*, 1976). There are two recent studies which give data on plasma 17OH-progesterone concentrations during the first 24 hours of life of newborn infants (Forest and Cathiard, 1978; Sippell *et al.*, 1978). Both report the rapid fall in plasma levels within hours of birth, reaching a nadir by about 5 to 7 days of age. The results now reported confirm and extend this observation in a larger group of infants also studied during the first week of life. As measurement of plasma 17OH-progesterone is so valuable in the early diagnosis of CAH, a comparison was made between results of plasma 17OH-progesterone determinations in normal and CAH infants. The data clearly show that, by 36 hours' postnatal age, there is a pronounced difference between the two groups.

Congenital adrenal hyperplasia is the most common cause of ambiguous genitalia of the newborn (Hughes, 1977). In many instances, plasma 17OH-progesterone measurements will also aid in the assessment of other conditions. In addition, some infants who are stressed—for example, due to infection—have concentrations of plasma 17OH-progesterone up to 30 nmol/l (10 ng/ml) at 5 to 7 days of age. However, plasma 17OH-progesterone concentrations exceed 200 nmol/l (68 ng/ml) in untreated CAH infants of this age.

Therefore, determination of plasma 17OH-progesterone concentrations in the neonatal period can be extremely useful for the differential diagnosis of ambiguous genitalia, electrolyte disturbances, or for the investigation of baby boys with a positive family history for CAH (Hughes and Winter, 1977). It is recommended that plasma samples should be collected after 24 hours' postnatal age in order to eliminate the placental influence on plasma 17OH-progesterone levels. The exact age of the infants, in hours, at the time samples are collected should be known.

We thank Professor O. P. Gray for permission to study infants under his care in the newborn nursery, University Hospital of Wales, and Mr D. W. Wilson for the statistical analyses. The continuing financial support of the Tenovus Organisation is greatly appreciated.

Continuing need for mineralocorticoid therapy in salt-losing congenital adrenal hyperplasia

I. A. HUGHES, A. WILTON, C. A. LOLE, AND O. P. GRAY

Department of Child Health and Tenovus Institute, and KRUF Institute of Renal Disease, Welsh National School of Medicine, Cardiff

SUMMARY Four patients with salt-losing congenital adrenal hyperplasia (CAH) who had stopped mineralocorticoid therapy for several years, showed raised plasma concentrations of 17OH-progesterone and plasma renin activity, despite adequate glucocorticoid therapy. One patient was able to reduce urinary sodium excretion when the sodium intake was restricted. Another patient who was a salt-loser, developed signs of an adrenal crisis when salt deprived. In comparison, one nonsalt-loser and 2 normal subjects decreased urinary sodium excretion in response to sodium restriction. The addition of fludrocortisone (100 μg) to usual maintenance doses of glucocorticoid, resulted in normal levels of plasma 17OH-progesterone and plasma renin activity in all 4 salt-losers. Two female salt-losers, with raised plasma testosterone concentrations, began menstruating when their plasma testosterone concentrations returned to normal after treatment with fludrocortisone. It is recommended that salt-losing CAH patients should be given mineralocorticoid, in addition to glucocorticoid therapy, at least until adult life.

About one-third to one-half of patients with congenital adrenal hyperplasia (CAH) due to C21-hydroxylase enzyme deficiency are salt-losers. This loss occurs within the first 2 weeks of life and patients require immediate mineralocorticoid replacement. However, they appear to require less salt later and it has been suggested that mineralocorticoid therapy can be discontinued at age 4 years (Newns, 1974). There is evidence that this regimen will lead to inadequate control in these patients. A pronounced increase in plasma concentrations of 17OH-progesterone and plasma renin activity occurs in some salt-losers, in spite of apparently adequate glucocorticoid replacement (Hughes and Winter, 1976; Grant *et al.*, 1977). The consequences of persistent raised levels of plasma steroid precursors are unknown. A group of salt-losing CAH patients, in whom mineralocorticoid treatment had been discontinued for several years, was studied to evaluate the metabolic responses to a restricted sodium diet and the reintroduction of mineralocorticoid therapy.

Patients and methods

Six patients with CAH due to C21-hydroxylase deficiency were initially included in the study. One boy, however, developed a salt-losing crisis as a result of gastroenteritis. Mineralocorticoid treatment was restarted and he was excluded from the study. Clinical details of the remaining patients are shown in Table 1. The salt-losers had hyponatraemic dehydration and hyperkalaemia soon after birth. They were treated with hydrocortisone (or cortisone acetate), fludrocortisone, and supplemental salt in the milk feeds. For comparison, a 13-year-old girl with nonsalt-losing CAH and two female student dietitians without evidence of endocrine disease were also studied.

Dietary histories were recorded for each patient, with particular reference to sodium intake. Patients were maintained on their usual doses of glucocorticoid during the study. Venous blood was collected between 0900 and 1000 hours for determination of plasma concentrations of 17OH-progesterone, testosterone, and plasma renin activity. 24-hour urine collections were performed for measurement of sodium and potassium excretion. Patients and controls were then placed on a dietary intake of 20 mmol sodium/day (potassium 75 mmol/day) for 4 days under supervision in hospital. Plasma and urinary studies were repeated at the end of this

period, when venous blood was collected from subjects in the standing position. Salt-losers were then treated with fludrocortisone 100 μg daily in addition to their usual glucucorticoid therapy. Measurement of plasma concentrations of 17OH-progesterone, testosterone, and plasma renin activity was repeated after 3 months.

Plasma 17OH-progesterone was determined by radioimmunoassay using an antiserum supplied by Dr D. L. Loriaux, NIH, USA. The sensitivity of the assay was 4 pg/tube. The intra-assay and interassay coefficients of variation were less than 6·3 and 11·9% respectively. Apart from 11-deoxycortisol (1·8%) and 21-deoxycortisol (1·6%), the cross-reactivity of the antiserum with numerous other corticosteroids, including progesterone, was less than 0·1%. Plasma testosterone was measured by radioimmunoassay as previously described (Hillier *et al.*, 1973). Plasma renin activity was measured by radioimmunoassay of the angiotensin I generated after standard incubation of plasma (Haber *et al.*, 1969). The mean level of plasma renin activity in healthy ambulant adults was 1·17±0·5 SEM ng/ml per hour.

Results

When studied, all salt-losers were taking more than 200 mmol sodium per day in their diet apart from table salt added to food. The results of baseline studies performed while on this sodium intake are shown in Table 2. The mean plasma 17OH-progesterone concentration in salt-losers was markedly raised, despite a hydrocortisone dose in the range of 20–32 mg/m^2 per day (mean dose 25 mg/m^2 per day). Two female salt-losers showed raised plasma testosterone concentrations and plasma renin activity was increased in all salt-losers. In comparison, the nonsalt-loser had normal plasma 17OH-progesterone and testosterone concentrations and a slightly raised plasma renin activity. All values were normal in the control subjects. The effects of sodium restriction in the control subjects and the nonsalt-loser (Case 5) are shown in Fig. 1. All showed a slight increase in plasma 17OH-progesterone concentrations and a rise in plasma renin activity, which was more pronounced in the nonsalt-loser. Urinary sodium excretion decreased to approximately 20 mmol/day in all 3 subjects in response to sodium restriction. Results obtained in one salt-loser (Case 1) are shown in Fig. 2. This patient was also able to reduce urinary sodium excretion, but the increases in plasma renin activity and plasma 17OH-progesterone were more pronounced. Fig. 3 shows the results obtained in two other salt-losers (Cases 2 and 4). Plasma 17OH-progesterone concentrations in both patients were markedly raised before the dietary period and increased further after sodium restriction. Neither patient was able to suppress urinary sodium excretion in response to a low sodium intake, nor was there an apparent change in levels of plasma renin activity. Unfortunately, neither patient in this instance was sampled for plasma renin activity in the standing position (Haber *et al.*, 1969). The 4th salt-loser (Case 3) did not tolerate the diet (Fig. 4). concentrations increased further from the previous high values and plasma renin activity increased to 60 ng/ml per hour. There was a 3 kg loss in body weight and the patient showed signs of an adrenal crisis after only 2 days' salt restriction. The study was discontinued and IV saline was given. This treatment, together with subsequent fludrocortisone therapy, resulted in plasma 17OH-progesterone concentrations and plasma renin activity returning towards normal levels and a regain to normal body weight. Urinary sodium excretion was not measured in this patient.

The results of hormone measurements performed after 3 months of treatment with 100 μg fludrocortisone are shown in Table 3. For comparison, the results of baseline studies (Table 2) are also given. The dose of glucocorticoid had remained constant

during this time. The mean plasma 17OH-progesterone concentration was now less than 30 nmol/l (9·4 ng/ml), considered normal for adequately treated CAH patients (Chaussain *et al.*, 1974; Hughes, 1977). Plasma testosterone concentrations and levels of plasma renin activity were also normal. During this time, 2 female salt-losers had started menstruating.

Discussion

This study confirms the suggestion that older children with salt-losing CAH can tolerate a reduction or even a cessation in mineralocorticoid treatment. However, this is compensated for by a high salt intake. The excessive sodium intake may be harmful over a long period. In their study of 3 children with hypoaldosteronism, Hamilton *et al.* (1976) suggested that in the face of sodium depletion, continuing a high sodium intake may have the effect of producing a high filtered water load in the kidney. This may in turn reduce renin production and hence the stimulus for aldosterone secretion. In such a situation, it is more rational to increase sodium reabsorption using a salt-retaining hormone. A high salt intake in childhood may be associated with the subsequent development of hypertension in adult life (Rose, 1977).

In this study, persistent salt depletion was suggested by increased levels of plasma renin activity in all but one of the salt-losers, despite normal serum electrolytes. This agrees with previous observations that measurement of plasma renin activity is an extremely sensitive index of sodium balance in salt-wasting disorders such as CAH (Dillon and Ryness, 1975; Hughes and Winter, 1977). All the salt-losers showed markedly raised plasma concentrations of 17OH-progesterone, indicating poor control, although they were receiving a hydrocortisone dose (25 mg/m² per day) considered appropriate for maintenance therapy (Brook *et al.*, 1974; Hughes and Winter, 1976). Limal *et al.* (1977) have also recently demonstrated raised concentrations of plasma renin activity, 17OH-progesterone, and aldosterone in a group of salt-losers treated only with hydrocortisone.

Two female salt-losers in our study had increased plasma concentrations of testosterone. This was not surprising in view of the significant correlation between plasma concentrations of 17OH-progesterone and testosterone in prepubertal and adolescent female CAH patients (Hughes and Winter, 1978). Persistently raised plasma testosterone concentrations in adolescent girls may result in menstrual disorders and possibly in reduced fertility (Kirkland *et al.*, 1974). It may not have been mere coincidence, therefore, that these two female salt-losers started menstruating after fludrocortisone therapy and a return to normal plasma testosterone concentrations.

Salt restriction exaggerated mineralocorticoid deficiency in these salt-losers. The nonsalt-loser (Case 5) and one salt-loser (Case 1) were both able to reduce urinary sodium excretion in response to a low sodium diet, although compared with the controls, they both showed a greater rise in plasma renin activity. Two other salt-losers in our study (Cases 2 and 4) failed to suppress urinary sodium excretion while on the diet. Their high plasma 17OH-progesterone concentrations increased still further, but no rise in plasma renin activity was demonstrated owing to an error in sampling technique. Salt restriction precipitated an adrenal crisis in one patient (Case 3) who required parenteral saline therapy. This patient and the boy excluded from the study because of an episode of gastroenteritis are examples of a severer degree of salt-wasting. The results suggest a variable degree of salt deficiency even within the small group of salt-losers examined in this study. Some patients are at serious risk of developing a life-threatening adrenal crisis if their salt intake is restricted.

What factors contribute to poor control in these salt-losing patients? There is evidence that infusion of angiotensin II (a polypeptide stimulated by increased plasma renin activity) can directly stimulate ACTH release in normal subjects (Rayyis and Horton, 1971). A recent study of sodium balance in CAH showed a significant correlation between plasma concentrations of ACTH and plasma renin activity (Rösler *et al.*, 1977). The degree of ACTH stimulation was proportional to the amount of sodium loss. Salt depletion may itself result in chronic 'stress' and an enhanced ACTH production. The effect of increased ACTH production from whatever cause is an increased secretion of adrenal steroid precursors in CAH—such as progesterone, 17OH-progesterone, and 16OH-progesterone. These corticosteroids, when secreted in excess, have natriuretic activity in humans (Janoski, 1977). Their sodium-losing effect is probably through a competitive inhibition of aldosterone in the renal tubule, which explains the increased aldosterone production rates documented in nonsalt-losing CAH patients (Bartter *et al.*, 1968).

In our patients, adding fludrocortisone to their treatments resulted in normal plasma concentrations of 17OH-progesterone, testosterone, and plasma renin activity. The dose of fludrocortisone (100 μg) would not have provided sufficient glucocorticoid effect to account for this improvement. It must be concluded, therefore, that as glucocorticoid therapy remained unchanged throughout this study, these salt-losers were chronically salt depleted and improved after mineralocorticoid therapy. Grant *et al.* (1977) added fludrocortisone to the treatment of a larger group of salt-losers. Not all their patients responded with a decrease in plasma steroid and plasma renin concentrations. However, only 50 μg fludrocortisone was used and the patients were studied again after one month of treatment. Our results show conclusively that salt-losing CAH patients continue to require salt-retaining hormones throughout childhood and early adult life. Achieving normal sodium balance in such patients may well allow a reduction in glucocorticoid therapy and thereby an improvement in growth potential.

We thank Miss S. Chick, KRUF Institute of Renal Disease, Cardiff Royal Infirmary, for performing the assays of plasma renin activity. The technical assistance from members of the Supraregional Assay Service Laboratory in the Tenovus Institute is greatly appreciated. I. A. H. acknowledges the support of the Medical Research Council of Canada during the course of this study.

Effects of pethidine and its antagonists on the newborn

J. E. H. BRICE, T. A. MORELAND, AND C. H. M. WALKER

Departments of Child Health, Pharmacology and Therapeutics, Ninewells Hospital and Medical School, Dundee

SUMMARY Nalorphine and naloxone were compared as to their effectiveness as pethidine antagonists. 85 infants were divided into a control group comprising 19 newborn babies whose mothers did not receive pethidine and the babies received no antagonist, and three groups in which the mothers all received pethidine and the babies had either no antagonist (24), nalorphine IV (16), or naloxone IV (26). All the babies were assessed by measuring their neurobehavioural states and respiratory functions. A further 12 newborn babies had naloxone plasma levels measured by radioimmunoassay. Although standard doses of nalorphine effectively antagonised the depressive effect on respiration induced by pethidine, there was a pronounced and undesirable excitatory agonist action. Naloxone was not observed to have any agonist activity, but the recommended IV dose (0·01 mg/kg) had only a slight and delayed antagonist action as measured by respiratory function tests. A more rapid and improved antagonism was noted after this dose was doubled (0·02 mg/kg). The plasma elimination-phase half-life of naloxone after intravenous cord injection was about 3 hours.

The narcotic antagonist naloxone became available in the UK in 1976, but there are few reports of its use in newborn babies. Naloxone can restore respiratory function to normal after depression induced by pethidine (Evans *et al.*, 1976; Gerhardt *et al.*, 1977; Wiener *et al.*, 1977). Studies in animals and man have shown that the main advantage of naloxone over nalorphine is its freedom from agonist activity, while a disadvantage is that its effect after IV injection seems to be of short duration. However, Wiener *et al.* (1977) showed this effect could be prolonged to 24–48 hours or longer by a single, large IM injection. These workers also demonstrated the ability of naloxone to restore neurobehavioural function in the newborn babies of mothers who had received pethidine.

Nalorphine was the standard narcotic antagonist used in the newborn until the introduction of naloxone, but their antogonist activities have not been compared. This study was therefore designed to compare the action of these two drugs, to assess the effect of currently recommended doses of naloxone, and to determine its plasma levels and half-life in the newborn baby.

Methods

Informed written consent for the study was obtained from the parents before labour was established. Only babies born at term (37–42 weeks) after a normal pregnancy, labour, and delivery were studied; babies with a cord blood pH of $<7·25$, babies who did not respond to simple resuscitative measures, and babies with any significant abnormalities were excluded. 85 newborn babies were divided at random into four groups. In the control group (group 1, $n = 19$) the mothers had received no pethidine during labour and their babies received no antagonist. A few mothers received epidural analgesia and/or Entonox, but no other analgesic or sedative was used. In the other groups the mothers had received IM pethidine within 4 hours of delivery but no other analgesic or sedative, apart from Entonox. Treatment of the newborn was randomised so that group 2 ($n = 24$) received no narcotic antagonist, and group 3 ($n = 16$) received nalophine and group 4 ($n = 26$) naloxone between one and 2 minutes after delivery. The antagonist was injected directly into the cord vein as close to the umbilicus as

possible and 'milked' inwards before the cord was reclamped at the site of injection. Apart from 3 newborn babies who received 0·7 mg nalorphine at the start of the study, the dose of this drug was standardised at 0·5 mg. Group 4 were divided into two different dose regimens: the recommended IV dose (0·01 mg/kg$\simeq$0·035 mg) was given to 14 babies in group 4A and, after evaluating the results of this treatment, 12 babies (group 4B) were given double this dose (0·07 mg).

The newborn babies were assessed clinically in three ways. The wakefulness of each was recorded at 15, 30, and 90 minutes and again between 12 and 24 hours, using the six states described by Brazelton (1973). At 90 minutes and again between 12 and 24 hours the sucking reflex was assessed, using the method of Scanlon *et al.* (1974), and between 12 and 24 hours of age a Scanlon neurobehavioural score was performed by two paediatric registrars who were unaware of the treatment the mother and baby had received.

As part of the respiratory function assessment, the times from delivery to the 1st breath and to sustained respiration were noted, together with the routine recording of Apgar scores. During the definitive tests of respiratory function the babies were nursed in a heated cot in which the skin temperatures were maintained within the neutral thermal range (36·0–36·5°C) by servo-control. If possible the measurements were performed with the newborn in a stable state, although this was difficult in group 3. The main test of respiratory function was the measurement of carbon dioxide (CO$_2$) output, from which, together with heel prick arterialised capillary blood pCO$_2$, alveolar ventilation was calculated (alveolar ventilation = expired CO$_2$ × barometric pressure/pCO$_2$, corrected for temperature and humidity). These estimations and full blood–gas analyses were done at 15, 30, and 90 minutes and finally between 12 and 24 hours after delivery. Carbon dioxide output was determined using a technique derived from open-circuit methods previously described (Kappagoda *et al.*, 1974; Newell *et al.*, 1976; Evans *et al.*, 1977). Expired CO$_2$ was measured using an infrared gas analyser*, and the overall error of the calculated expired carbon dioxide output with this system was less than ± 5% (Thompson *et al.*, 1979). Statistical evaluation was done with Student's *t* test.

Heel prick blood samples were collected from a separate group of 12 newborn babies for determination of plasma naloxone levels by radioimmunoassay. It was necessary to use different babies because sampling disturbed the baby sufficiently to invalidate the respiratory function result as representing the 'basal' state. Half of them had received 0·035 mg and half 0·07 mg naloxone injected into the umbilical vein. The assay was such that 2 ng naloxone displaced the radiolabelled tracer, ^{3}H-naloxone, by 50%. The presence of pethidine in concentrations of up to 400 ng per sample caused no displacement. Each assay was carried out in duplicate with 0·2 ml heparinised plasma. Although the main metabolites of naloxone were not available to test for crossreactivity, current evidence suggests that they would be unlikely to interfere with the assay in the concentrations likely to be found in plasma (Berkowitz *et al.*, 1975).

Results

The items of clinical relevance are shown in Table 1. The mean maternal pethidine doses and the mean pethidine-to-delivery time intervals of the three groups of mothers receiving pethidine were not significantly different. Despite randomisation the difference between the mean birthweights of the no antagonist babies and those in group 3 was significant ($P<0·05$), but when compared with the mean birthweights of the other groups this was probably not of clinical importance. That the newborn had not been subject to intrauterine hypoxia is suggested by the normal cord blood pH findings, the slight differences

Nalorphine (group 3, n = 16)	106 (17)	108 (56)	3388 (382)	7·34 (0·05)	7·8 (0·9) P<0·01	52 (41) P<0·01
Naloxone (group 4, n = 26)	112 (33)	93 (49)	3469 (446)	7·35 (0·04)	7·8 (0·7)	56 (30)

between the groups being of no significance. There was, however, evidence of pethidine intoxication as reflected in the Apgar score, the mean one-minute value of 7·6 for the no-antagonist group being lower than the 8·3 for the control group ($P<0{\cdot}002$). Likewise, failure to establish respiration normally was seen in the 3 pethidine-treated groups in that the time to sustained respiration was prolonged (52–56 seconds) when compared with the control group (30 seconds, $P<0{\cdot}01$). Groups 3 and 4 showed a similar initial degree of respiratory depression, but because of the smaller numbers the differences were not all of statistical significance.

The Brazelton state score indicated that the newborn babies in all groups were in a rather wakeful condition for the first 90 minutes (range of mean scores 3/6 to 5/6) but that they had settled by the 12–24-hour assessment (range 1·7/6–1·9/6). Infants in group 3 tended to be fretful and irritable with high pitched cries, and their scores were appropriately high (range 5/6–6/6 at 15 and 30 minutes). This was associated with a poor mean Scanlon sucking score at 90 minutes of 1·0/3 compared with > 1·9/3 for the other groups. By 12–24 hours there was a difference in the sucking scores between the controls (1·3/3) and group 3 (1·8/3), but there was no obvious difference between the no-antagonist and the antagonist-treated groups. There was no significant difference in the mean and decrement values for the Scanlan and neurobehavioural scores (group 1, 18·00 ± 6·18 and 18·33 ± 6·93; group 2, 19·23 ± 3·98 and 15·31 ± 6·29; group 3, 18·57 ± 4·22 and 14·47 ± 8·61; group 4A and B, 18·07 ± 4·46 and 17·5 ± 5·26).

Multiple statistical comparisons were made between the mean pH, pO$_2$, pCO$_2$, and base deficit measurements from each group. Many of the differences were statistically significant (e.g. pH at 15 and 90 minutes between group 1 and 2, $P<0{\cdot}001$; pH at 15 minutes between group 1 and group 4A, $P<0{\cdot}05$, and group 4B, $P<0{\cdot}001$). The results show that there was respiratory depression in group 2 and even in group 4A. Babies in group 4B fared rather better, and these trends are in keeping with the results of the specific respiratory function studies that follow.

Tables 2 and 3 show the values for total expired carbon dioxide (CO$_2$ output) and alveolar ventilation in the four groups. At all times group 2 showed a consistent reduction in both these parameters compared with group 1 ($P<0{\cdot}01$ for CO$_2$ output at 15 and 30 minutes and alveolar ventilation at 15 minutes). By 12–24 hours the difference in CO$_2$ output was less significant ($P<0{\cdot}02$) and the differences in alveolar ventilation were no longer significant.

In group 3 the values for CO$_2$ output and alveolar ventilation were consistently higher at 15, 30, and 90 minutes than those of group 1. They were also significantly higher than those of group 2 at 15, 30,

and 90 minutes with a smaller nonsignificant difference at 12–24 hours. Although the former were not statistically significant they do reflect a state of hyperventilation in group 3 compared with both the groups 1 and 2, and this was also manifest in a reduced capillary pCO_2 at 90 minutes.

After the lower naloxone dose in group 4A, CO_2 output and alveolar ventilation at 15 and 30 minutes were similar to those in group 2, indicating inadequate antagonism, and there was a significant reduction in CO_2 output ($P<0\cdot05$) in this group compared with the controls (group 1). However, there appeared to be a delayed naloxone effect with alleviation of respiratory depression at 90 minutes, the lack of statistical significance in this trend being due perhaps to the small number of cases.

In group 4B there was an improved initial antagonism. However, the values for alveolar ventilation (and capillary blood–gases) suggest that reversal of respiratory depression was not complete (Table 3). Compared with group 2, the CO_2 output was significantly higher at 15 minutes ($P<0\cdot01$) and at 30 minutes ($P<0\cdot05$) (Table 2). By 90 minutes the CO_2 output differences between groups 1, 2, and 4B were no longer significant but the values for both CO_2 output and alveolar ventilation suggested continuing antagonism.

In groups 2, 3, and 4 the alveolar ventilation values were correlated against the pethidine-to-delivery intervals of 0–1, 1–2, 2–3, and 3–4 hours. While there was obviously less respiratory depression in the 0–1-hour interval group, the differences were not significant, probably again due to the few infants in each group.

The results for the serial blood–gas analyses, the Brazelton and Scanlon scores, and the relation of alveolar ventilation to the pethidine-to-delivery intervals are not presented in full.*

The radioimmunoassay method was sensitive enough to enable naloxone levels to be followed for up to 4 hours after drug administration (Moreland *et al.*, 1979). Peak plasma levels of 4·0 to 20·2 ng/ml (mean 11·0) were observed during the first 40 minutes. Concentrations at the end of 4 hours ranged from 1·4 to 6·6 ng/ml (mean 4·2). In 4 newborn babies the drug concentration fell rapidly during the first 40 minutes and then declined more slowly, with an initial (distribution-phase) half-life calculated in one baby of 8 minutes. No such distribution phase was observed in the others and in 4 babies the plasma drug concentration increased during the first 20 to 40 minutes. The elimination-phase (mean ± SD) half-life calculated from all 12 newborn babies was 185 ± 108 min. The apparent volume of distribution determined by extrapolating the elimination phase curve was 1·99 ± 0·28 l/kg and the plasma clearance rate was 0·57 ± 0·12 l/kg per hour. There was no significant difference in the half-life, apparent volume of distribution, or clearance values between the newborn given 0·035 mg and 0·07 mg naloxone.

Discussion

The fact that relatively few cases were suitable for study during the 18 months of this project was due to the very strict criteria for selection, every effort having been made to eliminate all newborn babies with other depressant and complicating perinatal factors. During the study over 60% of the mothers received pethidine analgesia at some stage. The total dose received was relatively small and it was rare for a mother to be given a second dose, epidural anaesthesia being used if necessary. Despite this frequent but careful use of pethidine, our results confirm that significant depression of respiratory function was produced in these babies and, although slight, the differences were still apparent 12–24 hours after delivery. The fact that the effects of pethidine can be detected for even longer has been confirmed by Cooper *et al.* (1977) who found that it may take the newborn 3 to 6 days finally to eliminate the drug. Although not presented in detail, the respiratory function results were divided according to the pethidine-to-delivery time interval, and more obvious respiratory depression was found when the pethidine had been administered more than one hour before delivery.

Clinical assessments tend to be subjective and our preliminary observations of the state of wakefulness and of the sucking reflex were not performed under double-blind conditions. However, the pronounced excitatory effect of nalorphine was obvious and this confirms the clinical impression of hyperexcitability held previously. The Scanlon behavioural score, performed at 12–24 hours under double-blind conditions, indicated that there were no differences between the four groups. This differs from the findings of Brackbill *et al.* (1974), and may be due to the small numbers, to the timing, or to the subjective nature of the test. More objective tests such as those adopted by Wiener *et al.* (1977) to assess feeding, sucking, and habituation to an auditory stimulus are probably more accurate and reliable.

Nalorphine, although an effective antagonist to pethidine in terms of restoration of respiratory function, had an obvious excitatory effect, although it was not possible to estimate how much of the improvement was due to the narcotic antagonism and how much to stimulant effects. The most pronounced excitatory evidence of nalorphine was seen in the babies whose mothers had received pethidine within one hour of delivery, the group in which the babies were less likely to be depressed. No evidence of depressant effects of nalorphine were observed.

Since this study was completed nalorphine has been withdrawn from the market, so naloxone is now the only neonatal narcotic antagonist. As expected, no agonist activity of naloxone in the two doses used was observed. However, the results suggest that the recommended IV dose (0·01 mg/kg) when given as a bolus injection into the cord is ineffective at 15 and 30 minutes in reversing pethidine-induced respiratory depression. The apparent delayed effect (at 90 minutes) of the smaller dose could be a random finding related to the fewer cases. A more probable explanation, and one compatible with data on naloxone plasma levels, is that the drug is retained in the umbilical vein and ductus venosus, so delaying the distribution into the systemic circulation.

An improved and more rapid effect was seen with the larger (0·02 mg/kg) dose which may have been flushed more rapidly into the systemic circulation because of the larger volume. The purpose of this work was to study the antagonists in the circumstances most likely to be found in everyday obstetric practice, so the effects of umbilical catheter or peripheral IV injection, which have practical disadvantages when dealing with the acutely depressed newborn, were not studied.

Evans *et al.* (1976) used alveolar pCO_2 in the calculation of alveolar ventilation, while we used capillary pCO_2 and it might be expected that the values in the two studies would differ slightly. Nevertheless, allowing for such differences in method, the general conclusions about the effects of IV naloxone are similar. Evans *et al.* (1976) and Wiener *et al.* (1977) studied IV naloxone at one dose only (0·04 mg) and our results support their finding that the effect of such a dose is transient, and they even suggest that the dose can safely be doubled. The results of a large IM dose of naloxone (0·2 mg) (Wiener *et al.*, 1977) are impressive, and demonstrate a prolonged effect. The values for CO_2 output (7·1–7·5 ml/min per kg) and alveolar ventilation (190·0–194·4 ml/min per kg) at 12–48 hours are very high compared with our own control values at 12–24 hours and with other reported figures (Nelson *et al.*, 1962). A large dose of naloxone may have an effect on respiratory function other than purely narcotic antagonism. The findings almost suggest that this massive dose is exerting an excitatory effect similar to that found in nalorphine-treated babies. This explanation is supported by the work of Bramwell and Bradley (1974) in which both nalorphine and naloxone were found to exert an effect at the locus for the excitatory effects of morphine. Whether levels of naloxone rise sufficiently rapidly after IM injection to obviate the need for an IV dose in the acutely depressed and asphyxiated newborn baby is still uncertain. Possibly the acutely depressed baby should be given an IV dose followed by a larger IM one.

The elimination-phase plasma half-life of naloxone in the newborn (3 hours) was considerably longer than that in the adult (one hour) (Ngai *et al.*, 1976). This is probably due to immaturity of the drug-metabolising enzyme systems in the newborn. This reduced rate of elimination after comparable dosage would be expected to lead to longer duration of action of naloxone in the infant compared with the adult, longer than the 30 minutes suggested previously (Evans *et al.*, 1976; Wiener *et al.*, 1977).

We confirm that large IV doses of naloxone, unlike nalorphine, do not have any obvious narcotic agonist activity in the newborn child. To produce rapid and effective narcotic antagonism, the recommended IV dose of naloxone could be safely doubled to 0·02 mg/kg and perhaps increased even more. As respiratory depression was detectable after treatment with antagonist, even in the entirely normal baby, it must be much more important to ensure adequate treatment in the asphyxiated, the preterm, or the otherwise at risk infant. The elimination-phase plasma half-life of naloxone after IV administration was about 3 hours, considerably longer than in the adult. Further studies are required to evaluate the most effective dosage, timing, and mode of administration.

We are indebted to Dr J. Thompson (Department of Physiology, University of Dundee) for his design and construction of the gas mixing chambers for the carbon dioxide output measurements and to Dr C. Ingram (Department of Physiology, University of St Andrews) for advice on the respiratory function tests. We thank Mr A. Whytock and Mr W. M. Tocher (Department of Child Health), Mr A. R. Rimmer (Department of Medical Physics), and Professor P. D. Griffiths and staff (Department of Biochemical Medicine), all of the University of Dundee, for technical assistance, Dr J. Bell and Dr S. Ackroyd for assessing the Scanlon scores, Mrs B. Forsyth and Miss L. Henderson for secretarial work, and all the nursing staff in the maternity department for their help. Dr G. W. Aherne (University of Surrey) kindly supplied the antiserum.

The work was supported by grants from the Wellcome Trust, Winthrop Laboratories, and the Tayside Area Health Board.

Creatine phosphokinase levels in the newborn and their use in screening for Duchenne muscular dystrophy

L. M. DRUMMOND

University of Auckland School of Medicine

SUMMARY The PKU sample, if taken after the 3rd day, is suitable for Duchenne muscular dystrophy screening using creatine phosphokinase (CPK) levels. 101 babies (53 girls and 48 boys) had CPK levels measured on filter paper blood specimens taken by heel prick on the 1st and 4th days of life. The method used was that described by Zellweger and Antonik (1975). The CPK levels were markedly raised on the 1st day of life but by the 4th day they had reduced to within 3 times the upper limit of the normal range for adults. 10 000 boys were then screened for Duchenne muscular dystrophy using the PKU sample, and 2 cases were found.

Duchenne muscular dystrophy (DMD) has a reported incidence of 1 in 3600 to 1 in 5600 live male births (Morton and Chung, 1959). It is inherited as an X-linked recessive condition and considered to be genetically lethal in boys as affected people do not reproduce. Calculations show that to maintain the incidence in the population, one-third of new cases with no family history must be fresh mutations. Thus carrier detection is very important for the mother and other female relatives.

The creatine phosphokinase (CPK) level is greatly raised in DMD, sometimes up to 30 or 40 times the upper limit of normal for adults. This led Zellweger and Antonik (1975) to suggest that screening of newborn boys for DMD could be carried out by measuring the CPK levels in the dried blood spots normally collected for PKU testing. Any persistent increases would be followed up by serum CPKs, clinical examination, and EMG studies. Early detection of affected infants identifies those mothers and female relatives who should be fully investigated to determine their carrier status before further pregnancies are considered.

The difficulty is that greatly increased CPK levels during the first few days of life have been found in normal newborn babies (Rudolph and Gross, 1966; Bodensteiner and Zellweger, 1971; Gilboa and Swanson, 1976). These increased levels have been attributed to birth trauma but no clear correlation has been established.

The aim of this study was (1) to investigate the blood levels of CPK in the neonatal period to establish whether blood taken on the 4th day (as used for PKU testing) would be satisfactory for DMD screening, and (2) to look at DMD screening in a defined population using the PKU specimen.

Methods

The population sample comprised 101 consecutive live births at St Helen's Hospital, Auckland, New Zealand. Two specimens (dried blood spots from heel pricks) from each infant were assayed; one had been collected within 24 hours of delivery and the other was one routinely taken for PKU screening on the 4th day. The CPK levels were measured using the 'CPK-screen' kitset (Antonik Laboratories) and a Chem-Glow photometer (American Instrument Company).

The CPK activity of the dried blood spot was expressed in arbitrary fluorescent units, in which one unit is equivalent to the meter reading on the Chem-Glow photometer using the 0–100 scale with multiplier switch in position 1. Capillary blood samples from 25 normal adults were collected on filter paper cards and assayed by the standard technique to establish a normal adult range. Data were also recorded about the pregnancy and delivery. Variables considered were birthweight, duration of 1st and 2nd stages of labour, number of pregnancies, maturity of fetus, and method of delivery.

10 000 consecutive liveborn male infants from the Auckland and Northland area were screened

Department of Community Health, University of Auckland School of Medicine, New Zealand
L. M. DRUMMOND, research fellow

for DMD using the method described above. The specimens used were the PKU samples collected for the National Testing Centre. Greater than 20 SDs above the batch mean was taken as a positive result. Any positive result was retested, and if it was still greatly raised, a liquid blood sample was requested for a serum CPK estimation, and the baby referred to a paediatrician for evaluation. To investigate the possibility of false-negative results, those specimens with CPK levels outside 3 SDs of the mean of the batch were repeated and, if they remained raised, a 2nd dried blood specimen was requested.

Results

The CPK levels for all samples taken on days 1 and 4 are shown in Table 1. Analysis of day 4 levels gives a 95% confidence range of 13–77. This compared with an adult 95% confidence range of 3–34, and an adult mean of 18·5 with a SD of 7·9. Multiple regression analysis of the variables—birth weight, duration of 1st and 2nd stages of labour, number of pregnancies, and maturity of fetus—was carried out on the data obtained for those babies who were delivered vaginally (93 babies). The correlation coefficient of birthweight with the CPK level was 0·29 ($P<0.01$) and the correlation of the duration of 1st stage labour with the CPK level was 0·26. Multiple regression showed the correlation coefficient of both birthweight and duration of 1st stage of labour with the CPK level to be 0·36 ($0{\cdot}01<P<0{\cdot}05$).

Table 2 shows levels of CPK found for each method of delivery on days 1 and 4. This is further illustrated by the Figure. Statistical analysis of the CPK levels on day 1 showed a significant difference between vaginal and vaginal with forceps deliveries ($P<0{\cdot}01$), and between elective and emergency caesarean sections ($P<0{\cdot}02$). There was no significant difference between vaginal deliveries and elective caesarean sections ($t_{79} = 0{\cdot}6204$).

The 10 000 male infants screened showed a wide range of ages at which the PKU specimen was taken. An analysis by days of a random sample of 2217 out of the 10 000 is given in Table 3. The CPK levels found on day 2 were not significantly different from those found on day 3 or on day 4. Analysis showed that the negative regression of the CPK values on the age at which the PKU specimen was taken was not statistically significant.

Two greatly raised values were found—1400 and

1000 arbitrary units (PKU samples both taken on 4th day of life). These were respectively 161 and 94 SDs outside their batch means, and liquid blood specimens showed greatly raised serum CPK levels (3044 and 3000 IUs respectively). Physical examination of the two boys was normal. A muscle biopsy confirmed the diagnosis in one and, in both babies, the CPK remains at a greatly raised level. In neither case was there a history of DMD.

In the group of boys with CPK levels >3 SDs, one had on day 5 a CPK level between 5 and 6 SDs outside the batch mean but showed a greatly raised CPK at age 6 months. A liquid blood serum CPK level confirmed the greatly raised CPK levels (>2000 IU). On physical exmination the baby is normal and there is a family history of Becker muscular dystrophy.

Discussion

It has been suggested that the PKU blood sample would be ideal for DMD screening (Zellweger and Antonik, 1975; Beckmann *et al.*, 1976), but others feel that the CPK levels in the immediate neonatal period are too variable to make screening for DMD reliable (Gilboa and Swanson, 1976).

This study confirmed the variability of CPK levels in the 1st 24 hours but by the 4th day even greatly raised levels, as high as those associated with DMD (30 to 40 times the upper limit of normal adult range), had come down to within 3 times the upper limit of the normal adult range. The two highest levels found in two girls—1150 and 810—had reduced to 65 and 27 respectively by the 4th day. This confirms that if the PKU sample is taken after the 3rd day of life, the sample is suitable for DMD screening. As can be seen in the Figure, two CPK levels in the vaginal delivery category actually increased from day 1 to day 4, one from 66 to 86 and the other from 90 to 97. Both are still within 3 times the upper limit of normal for adults, and the increase can be explained by the error of the method. Triplicate determinations on 53 specimens showed the standard error of one measurement to be 8%. There was no significant difference in CPK levels between boys and girls on either day 1 or day 4. This would be in agreement with Demos (1971), who found no difference between boys and girls when he excluded boys with preclinical DMD.

The significant difference between CPK levels for normal vaginal deliveries and vaginal deliveries with forceps (not Wrigley's), and that between CPK levels for elective caesarean section and emergency caesarean section are indicative of difficult labour being associated with raised CPK levels. Rudolph and Gross (1966) suggest that hypoxia may damage the muscle cells and thus increase the CPK levels. There may be other causes of damage but the actual mechanism is still unclear. Birthweight and duration of 1st stage labour were the two birth variables that had a significant correlation with the CPK level, but this only explained 13% of the variations in CPK levels.

More significant factors may be the relationship between the configuration of the mother's pelvis and the baby's weight, the strength of uterine contractions and number and duration of periods of hypoxia, but these are very difficult to assess. It is interesting to note that in two cases, maternal pyrexia was present and the infants' CPKs on day 1 were 1150 and 470. This could be due to a viral infection in the child causing a myositis and thus raised CPK levels.

From the 10 000 babies tested, the incidence of DMD in the north of the North Island of New Zealand can be calculated to be 1 in 5000. This is comparable with the incidence estimated from the pooled data of Morton and Chung (1959) but lower than that found in Germany (Beckmann *et al.*, 1976).

The two DMD cases detected had CPK levels that were much higher than the values found for other infants. It seems there is a clear-cut distinction between 'normal' values for infants and values for preclinical DMD sufferers. However the milder X-linked Becker muscular dystrophy may not be detected by screening at an early age unless the threshold for a positive test is lowered to include a large number of false-positives.

In all three cases of confirmed muscular dystrophy, genetic counselling and carrier detection were offered. There was no family history in either case of DMD. Carrier detection studies were normal for one mother and abnormal for the other, so she intends limiting her family and having her only daughter tested when she reaches child-bearing age. Unfortunately the parents of these two cases of DMD are immigrants to New Zealand and their relatives live in Bermuda and Fiji where the carrier tests are probably not available.

The mother of the child with presumed Becker muscular dystrophy had normal carrier tests but only 60% of known carriers have raised CPK levels (Skinner *et al.*, 1975). She does not intend limiting her family as the two other affected family members have had only minor disabilities.

It has been suggested that parents wish to know about their child's condition as quickly as possible (Zellweger and Antonik, 1975; Beckmann *et al.*, 1976), but we found in the two DMD cases that this was not so. Information given at a very early stage may not be well received by parents. They are extremely upset and are concerned about their child who looks so normal. At this stage, they are less concerned about the outcome of future pregnancies. It appears that the people who replied to the questionnaires on whether they would like to know early about their child having DMD (Zellweger and Antonik, 1975; Beckmann *et al.*, 1976), are thinking of the practicalities of the situation and not of the emotional problems.

The problem of screening for DMD when there is no known cure has been discussed (*British Medical Journal*, 1975; Dubowitz, 1976). Gardner-Medwin (1976) points out that genetic counselling given after a DMD case has been detected by screening may not be as effective as predicted. In fact, Roses *et al.* (1977) suggest that the time and money would be better spent on research into the underlying cause of DMD and better carrier detection. In theory, screening and genetic counselling with carrier detection would reduce the incidence of DMD by preventing the birth of a 2nd case in a family. However it may be difficult for parents to make informed decisions when they have not adjusted to the fact that their 'normal' son has DMD. It will be interesting to see the long-term effect of screening and genetic counselling for DMD in places where such programmes have been well established.

Conclusions

1. The PKU sample taken on the 4th day of life can be used for DMD screening as the CPK levels in normal babies are low enough to distinguish from the levels found in DMD.
2. Difficult labours are associated with higher CPK levels.
3. Birthweight is a significant factor in raised levels of CPK, but the actual mechanism is still unknown.

I thank Professor A. M. O. Veale, Dr I. C. T. Lyon, and Mr M. I. Parslow for their help.

Serum 25-hydroxy-vitamin D in hepatobiliary disease in infancy

AKIO KOBAYASHI, SAKAE KAWAI, MICHIKO OHKUBO, AND YOSHIRO OHBE

Department of Paediatrics, National Children's Hospital, Tokyo

SUMMARY Serum 25-hydroxy-vitamin D (25-OHD) concentrations were measured in 49 patients with hepatobiliary disease in infancy. Low mean values were found in groups of patients with biliary atresia, neonatal hepatitis, choledochal cyst, and chronic intrahepatic cholestatic syndrome. In the group of patients with surgically repaired biliary atresia, the mean value did not differ from normal. Parenteral vitamin D increased 25-OHD in serum in patients with biliary atresia, but did not do so in one patient with neonatal hepatitis. In contrast, oral vitamin D did not increase serum 25-OHD concentrations in patients with biliary atresia. It is concluded that the reduction of serum 25-OHD seen in biliary atresia was largely due to the malabsorption of vitamin D, while in neonatal hepatitis it was due to impairment of 25-hydroxylation of the vitamin.

Although rickets is a common complication in hepatobiliary disease in infancy (Yu *et al.*, 1971; Kobayashi *et al.*, 1974a), the mechanism underlying its pathogenesis is poorly understood. It can be postulated that the impairment of 25-hydroxylation of vitamin D in the liver may contribute to the pathogenesis of hepatic rickets. On the other hand, rickets in hepatobiliary disease may result from defective absorption of fat-soluble vitamin D because of deficient or absent bile flow into the intestine. The present study was undertaken to assess serum 25-hydroxy-vitamin D (25-OHD) concentrations in patients with hepatobiliary disease in infancy and to investigate the pathogenesis of hepatic rickets.

Subjects and methods

The subjects were 14 patients with biliary atresia, 22 with biliary atresia who had been successfully repaired by hepatic portojejunostomy and had no jaundice (Kobayashi *et al.*, 1976), 7 infants with neonatal hepatitis, 5 patients with chronic intrahepatic cholestatic syndrome, and one infant with choledochal cyst.

All patients with biliary atresia had laparotomy and the diagnosis was confirmed. Diagnosis of neonatal hepatitis was on clinical and laboratory grounds, excluding other diseases causing obstructive jaundice during infancy. Of 5 patients with chronic intrahepatic cholestatic syndrome, 3 had intrahepatic biliary hypoplasia (Alagille *et al.*, 1975) and the other 2 had recurrent intrahepatic cholestasis (Summerskill and Walshe, 1959). One infant with choledochal cyst had a laparotomy and the diagnosis was confirmed.

Radiological evidence of rickets was found in 7 (50%) of 14 patients with biliary atresia at the time of determination of serum 25-OHD. No lesions were observed in 22 patients with surgically repaired biliary atresias. In neonatal hepatis 3 (43%) of 7 patients had the lesion. In the group of patients with chronic intrahepatic cholestatic syndrome one patient with intrahepatic biliary hypoplasia had rickets. The infant with choledochal cyst had no radiological signs of rickets. The lesions in the present series were florid.

Serum 25-OHD was measured by a modified method of Belsey *et al.* (1974), using competitive protein-binding assay.

Results

Serum 25-OHD concentrations of control group. Serum 25-OHD was measured in 17 healthy infants and children. The mean value from age 2 months to 1 11/12 years was 22·4 ng/ml (n = 11, SD 9·5), with a range of 8·3 to 42·0. In the group above 2

YOSHIRO OHBE, chief clinical paediatrician

years of age it was 18·9 ng/ml (n = 6, SD 7·6), with a range of 12·5 to 30·0. There was no significant difference between the two age groups.

Serum 25-OHD concentrations in hepatobiliary disease (Fig. 1). In 14 patients with biliary atresia serum 25-OHD concentrations were conspicuously reduced with the mean value of 8·2 ng/ml (SD 5·2, range 2·0 to 17·5), which was significantly lower than normal ($P<0·001$). In contrast, the mean serum 25-OHD value for 22 patients with successfully repaired biliary atresia was 23·5 ng/ml (SD 11·0, range 6·0 to 43·5). The value was not significantly different from normal. In neonatal hepatitis the value was reduced to the same extent as in biliary atresia, with a mean of 9·2 ng/ml (SD 5·3, range 2·0 to 14·5). In chronic intrahepatic cholestatic syndrome serum 25-OHD was very low, with a mean of 6·4 ng/ml (SD 5·9, range 2·0 to 16·5). Patients with rickets generally showed low serum 25-OHD concentrations, while those whose serum levels were very low not always had radiological evidence of rickets. However, some of these patients with very low levels of serum 25-OHD and without rickets at the time of determination of serum 25-OHD, later showed radiological signs of rickets.

Effect of vitamin D on serum 25-OHD in hepatobiliary disease (Fig. 2). The effect of oral and parenteral vitamin D on serum 25-OHD was evaluated in 6 patients with biliary atresia. In 2 infants who had been given oral vitamin D 3000 IU daily, one for 2 and the other for 5 weeks, serum 25-OHD concentration did not change significantly (10·5 to 7·0, 13·5 to 13·5 ng/ml). In contrast, in 4 patients who had been given IM vitamin D 30 000 IU weekly for 2 to 12 weeks, serum 25-OHD concentration was enhanced, markedly in 2 (2·0 to 48·0, 7·5 to 27·0 ng/ml) and mildly in the other 2 (7·0 to 11·0, 15·0 to 18·0 ng/ml).

The effect of parenteral vitamin D on serum 25-OHD was evaluated in one infant with neonatal hepatitis in whom serum concentration before treatment was 2·0 ng/ml. On admission the patient suffered from tetany and haemorrhagic diathesis, while the stools were yellow in colour and serum bilirubin was 7·0 mg/100 ml (120 μmol/l). Serum 25-OHD was not raised, despite IM vitamin D 50 000 IU weekly for 2 weeks.

Comparative biochemical studies in hepatobiliary disease. The levels of serum alkaline phosphatase, calcium, magnesium, and phosphorus in each group were studied. Serum alkaline phosphatase level was raised in most patients with biliary atresia, neonatal hepatitis, or chronic intrahepatic cholestatic syndrome, and it was also raised in half of the patients with repaired biliary atresia. There was, however, no correlation between serum 25-OHD and alkaline phosphatase. Serum calcium levels were within the normal range in most patients with the

exception of 3 with biliary atresia, one with repaired biliary atresia, one with neonatal hepatitis, and one with intrahepatic biliary hypoplasia. Concentrations of phosphorous were within the normal range in all groups.

Serum 25-OHD did not correlate with any conventional liver function tests performed on these infants.

Discussion

There have been several reports on serum 25-OHD concentrations in adult patients with hepatobiliary disease, and the value is usually low (Haddad and Chyu, 1971; Hepner *et al.*, 1976; Long *et al.*, 1976; Wagonfeld *et al.*, 1976; Long *et al.*, 1978). However, we are unaware of any previous systematic survey of serum 25-OHD in infants with hepatobiliary disease. The present study showed low serum 25-OHD level in hepatobiliary disease in infancy, including biliary atresia, neonatal hepatitis, choledochal cyst, and chronic intrahepatic cholestatic syndrome. In biliary atresia, in which bile flow into the gut is absent, serum level was conspicuously reduced. In surgically repaired biliary atresia the value was enhanced to the normal range. In both neonatal hepatitis and chronic intrahepatic cholestatic syndrome serum 25-OHD was reduced to the same extent as in biliary atresia.

In the report by Daum *et al.* (1976), who studied serum 25-OHD in 5 cases of biliary atresia, the value ranged from 2 to 7 ng/ml. One case showed a normal level after surgical repair of biliary atresia despite the presence of secondary biliary cirrhosis. Their results were in general in accord with ours, but the range of the value in the present series was greater.

Our study showed that impaired 25-hydroxylation of vitamin D did not account for the low level of 25-OHD in biliary atresia, as serum 25-OHD was distinctly raised in at least 2 of 4 patients with biliary atresia who had received parenteral vitamin D. On the other hand, serum 25-OHD was not raised by treatment with oral vitamin D. These findings suggest that low serum level of 25-OHD observed in biliary atresia was attributable to the malabsorption of vitamin D rather than to the impairment of 25-hydroxylation of the vitamin. This conclusion accords with our previous report on the intestinal absorption of calcium and magnesium in hepatobiliary disease in infancy (Kobayashi *et al.*, 1974b). In the paper, it was shown that in biliary atresia parenteral vitamin D increased moderately the absorption of both elements, although oral vitamin D had little effect.

Rickets is a common complication in neonatal hepatitis (Yu *et al.*, 1971; Kobayashi *et al.*, 1974a), in which the malabsorption of calcium and magnesium has also been shown (Kobayashi *et al.*, 1974b). The present report showed a low serum level of 25-OHD in patients with the disease. The mechanisms underlying the pathogenesis of rickets in neonatal hepatitis, however, were different from those in biliary atresia. The impaired 25-hydroxylation of vitamin D may be responsible for the development of rickets in neonatal hepatitis to a greater extent than the malabsorption of vitamin D, as the present study showed that one infant who had been treated with parenteral vitamin D still had a low serum level of 25-OHD. This mechanism was also suggested by Antony and Beveridge (1975), who stressed the prematurity of infants with neonatal hepatitis. They stated that the small fat tissue and muscle mass of premature infants, the sites of storage for vitamin D, and the immaturity of hepatic enzymes in combination with hepatitis might have a role in the development of rickets.

From this study, and the previous one, it is reasonable to treat patients with rickets and biliary atresia with intramuscular vitamin D 30 000 IU weekly. In contrast, oral vitamin D is sufficient in mild or moderate cases of neonatal hepatitis in a dose of 2000 to 5000 IU daily for several weeks (Yu *et al.*, 1971), while infants with severely damaged liver parenchyma need oral 25-OHD, a more potent metabolite of vitamin D (Burmeister *et al.*, 1972; Daum *et al.*, 1976; Wagonfeld *et al.*, 1976).

We thank Professor T. Suda, Department of Biochemistry, Showa University School of Dentistry, for measurement of serum 25-OHD. This study was supported by the fourth Mitsukoshi Medical Award.

Relationship between urinary and blood glucose in diabetic children

N. K. GRIFFIN, M. A. SMITH, P. A. JENKINS, G. WERTHER, AND J. D. BAUM

Department of Paediatrics, John Radcliffe Hospital, Headington, Oxford

SUMMARY The relationship of urine glucose concentration with 'average' blood glucose concentration for the corresponding period was investigated in 10 juvenile diabetics during the performance of 15 inpatient metabolic profiles. 0% glycosuria was associated with 'average' blood glucose concentrations <6·4 mmol/l (<115 mg/100ml), 2% glycosuria with concentrations >8·6 mmol/l (>154 mg/100ml), and over 5% glycosuria with concentrations > 11·3 mmol/l (>204 mg/100ml). Urinary glucose loss was large (>278 mmol; >5g) when the 'average' blood glucose was >11·1 mmol/l (>200 mg/100ml). Because many diabetics have blood glucose concentrations up to 11·1 mmol/l, it is advantageous if glycosuria up to 5% is detectable by routine home urine tests. The 2-drop Clinitest method detects glycosuria up to 5% without significant loss of accuracy and is recommended in preference to the 5-drop method.

Diabetic control in children with diabetes is usually assessed by frequent measurements of urine glucose concentration. This test is performed by the child or his parents using a simple proprietary system. Clinitest tablets (Ames Company, Slough) are widely used and, in conventional use, 5 drops of urine plus 10 drops of water generate a colour indicating a reducing sugar concentration in the range from 0 to 2 g/100 ml (0 to 111 mmol/l). Alternatively, the 2-drop Clinitest method (Belmonte *et al.*, 1967) may be used; this uses 2 drops of urine plus 10 drops of water generating a colour range corresponding to a urinary-reducing sugar concentration from 0 to 5 g/100 ml (0 to 278 mmol/l).* Whichever system of urine testing is used, the urine glucose concentration is a retrospective and indirect measurement of the blood glucose concentration from the time that the bladder was last emptied. We studied the relationship between urinary and blood glucose concentrations measured over a 24-hour period in hospital in a group of diabetic children.

Methods

The study formed part of a larger investigation of metabolic profiles (N. K. Griffin *et al.* in preparation) performed on diabetic children to assess their total control. At the time of the study all the children were reasonably well controlled according to usual criteria. Informed consent was obtained from the children and their parents before admission to hospital, and throughout the study the children were on their normal diets and their physical activities were not restricted.

Fifteen 24-hour studies were performed on 10 children (3 girls and 7 boys). The ages of the children at the time of the study ranged from 10 to 16 years (mean 13·5) and they had been diabetic for 0·1–8 years (mean 4·2). All the studies were performed with the children on once-daily injections of insulin: 4 on Lente (unspecified manufacturer), 4 on Rapitard (Novo*), and 7 on Monotard (Novo*), with the daily dose ranging from 22 to 88 units (mean 47).

The patients were admitted to hospital in the evening and the study began the next morning. A plastic cannula was inserted into a peripheral vein and kept patent with heparinised saline between samplings. Blood samples were withdrawn for blood glucose measurements during the day before each main meal (7.30, 12.00, and 18.00 hours) and 15, 30, and 60 minutes after each meal. Samples were

also drawn before snacks (10.30, 15.00, and 20.30 hours) and during the night (23.00, 02.00, 05.00, and 07.00 hours). Samples for blood glucose were placed in 5% perchloric acid and the glucose subsequently measured using the hexokinase method (Bergmeyer, 1974).

Blood glucose measurements for each child were plotted against time and individual points were joined. From this line the blood glucose concentration was read at 30-min intervals throughout the 24 hours and the 'average' blood glucose concentration was calculated for each period between urine voidings.

Each urine sample voided was collected separately in plastic containers and the volume measured. An aliquot was placed in a separate fluoride tube, and the urine glucose concentration estimated using a glucose analyser with glucose oxidase (Analox Instruments).

The mean interval between voidings during the day was 2·7 hours (range 0·75–5). The overnight urine was passed as a single voiding in the morning: the mean time since the previous voiding for this specimen was 10 hours (range 8·5–11). The results of the overnight samples were analysed separately from the urine voidings and blood glucose measurements made during the day.

Results

Validation of the 2-drop urine test. 26 urine samples were tested for reducing sugar concentration using the 2-drop urine test and the corresponding glucose concentration was measured using the glucose analyser. The correlation is shown in Fig. 1. All but two Clinitest readings were accurate to within one colour reading on the 2-drop Clinitest scale but it was apparent that a reading on the Clinitest scale of 5% indicated a glucose concentration equal to, or greater than, 5 g/100 ml (278 mmol/l).

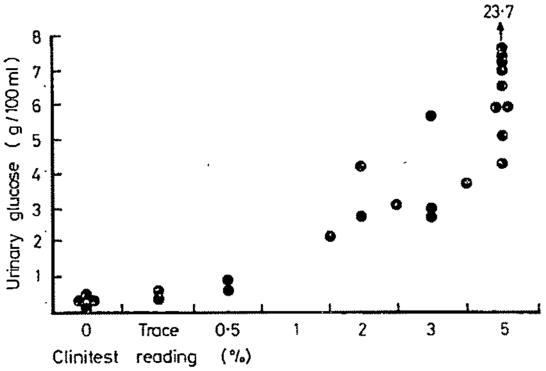

Fig. 1 *Correlation of the urinary glucose concentration measured by the glucose analyser and the Clinitest 2-drop method.*

Relationship between blood glucose concentration and urinary glucose concentration.

Night time period

There were 14 overnight urine collections. The relationship between the 'average' nocturnal blood glucose concentration and the urine glucose in the morning specimen is shown in Fig. 2. The correlation is poor and is not statistically significant.

Day time period

The relationship between the 'average' blood glucose concentration and the corresponding urinary glucose concentration during the day is shown in Fig. 3. The data relate to 10 children and represent 64 blood glucose/urine glucose pairs (r = 0·74; P<0·001).

Undetectable glycosuria occurred only with an 'average' blood glucose <6·4 mmol/l. 2% glycosuria indicated an 'average' blood glucose >8·6 mmol/l, and 5% glycosuria indicated a blood glucose >11·3 mmol/l.

The urine glucose excretion at each voiding was also measured. Fig. 4 shows that with an 'average' blood glucose <11·1 mmol/l (<200 mg/100 ml) the urinary glucose loss is small (<5 g; 278 mmol) but with >11·1 mmol/l considerable losses may occur.

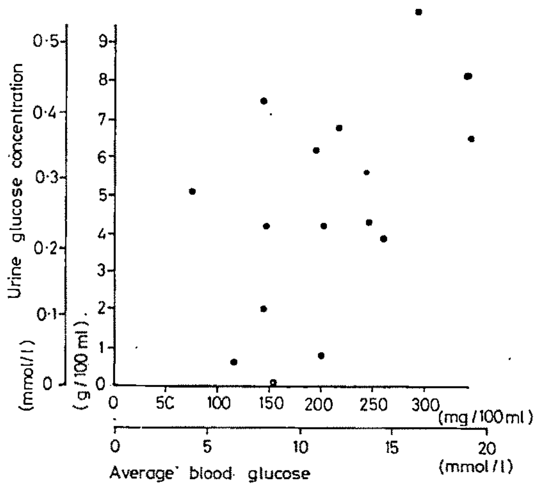

Fig. 2 *Relationship between the urinary glucose concentration in the first morning specimen and the 'average' nocturnal blood glucose concentration. The correlation is not significant.*

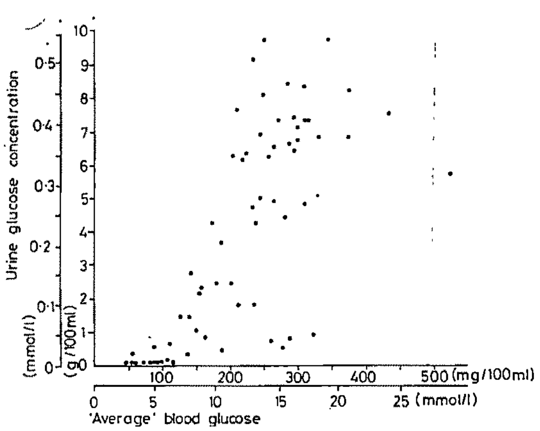

Fig. 3 *Relationship between the urinary glucose concentration and the corresponding 'average' daytime blood glucose concentration (P<0·001).*

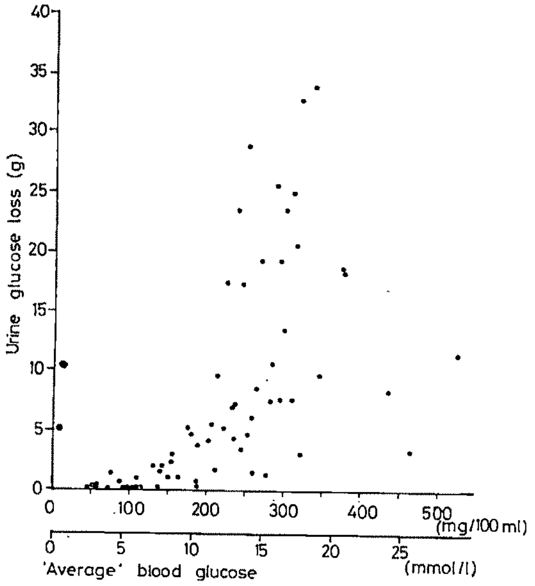

Fig. 4 *Relationship between the total urinary loss and the corresponding average daytime blood glucose concentration (P<0·001).*

Discussion

The day-to-day control of diabetic patients is currently judged principally on the urinary glucose concentration measured by the patient using a commercially available kit, such as Clinitest. In Britain the 5-drop method is often used but elsewhere the 2-drop method is more common. It is likely that urine testing will remain the primary index of diabetic control until systems for home monitoring of blood glucose (Sonksen *et al.*, 1978; Walford *et al.*, 1978) are simplified, especially in the case of diabetic children.

The usefulness of urinary glucose measurements in the management of diabetes depends on its accuracy in reflecting the blood glucose concentration. The two measurements are not constantly related as the urine glucose concentration will be influenced by the urine volume, the renal threshold for glucose, and the peak blood glucose levels reached between bladder voidings. These factors may alter from day-to-day because of variations in the patient's activity, fluid intake, and general health, and in qualitative changes in the carbohydrate eaten.

Overnight, changes in blood glucose concentrations occur more slowly but because of the longer time between bladder voidings they are not so accurately reflected by urinary glucose concentrations. The urine glucose may relate to the height of the postprandial blood glucose level the evening before, or to the rising blood glucose in the later hours of the night in patients in whom insulin activity does not completely cover 24 hours. It is, therefore, difficult to interpret the urine glucose concentration on the first specimen voided in the morning unless it is 0%.

During the day urine glucose concentrations give a valid retrospective index of blood glucose levels. Readings of 0% indicate a blood glucose concentration below the patient's renal threshold since the last urine specimen. Readings of 2% indicate an 'average' blood glucose >8·6 mmol/l, and levels of 5% indicate an 'average' blood glucose >11·3 mmol/l. Furthermore large quantities of glucose may be lost in the urine when the 'average' blood glucose is >11·1 mmol/l since the previous voiding (Fig. 4). In order to identify blood glucose concentrations of this level, urine glucose concentrations of 2–5% must be measurable. With Clinitest tablets this is only possible if the 2-drop method is used. The findings presented here confirm that the additional range of glycosuria detectable is of clinical value, and is achieved without any loss of accuracy at low levels of glycosuria.

Iron deficiency in children with coeliac disease on treatment with gluten-free diet

Role of intestinal blood loss

I. KOSNAI, P. KUITUNEN, AND M. A. SIIMES
Children's Hospital, University of Helsinki, Finland

SUMMARY 24 children in whom coeliac disease had been diagnosed between one and 10 years earlier were re-examined for intestinal loss of iron and activity of the disease. Mild iron deficiency by laboratory criteria and by response to iron medication was common. The children with biopsy evidence of flat mucosa or intraepithelial lymphocytosis had a greater iron loss in their stools than those patients with normal, or almost normal, histology, The data suggest that loss of iron was mainly due to intestinal blood loss rather than to shedding of mucosal cells. We conclude that treatment with iron is indicated in many children with coeliac disease as the increased losses of iron persist for long periods although absorption of iron seems to improve or be negligibly affected.

Mild iron deficiency is often found in patients with coeliac disease being treated with gluten-free diets (Visakorpi *et al.*, 1970; Shmerling and Zimmerli-Häring, 1971). The potential aetiological factors are decreased absorption of iron, increased loss of iron with the rapidly turning over epithelium cells, and pathological bleeding through intestinal tract (Sutton *et al.*, 1970; Anand *et al.*, 1977; Harms *et al.*, 1977). However, impaired absorption is less likely to be the reason for iron deficiency as ferrous iron generally seems to be better absorbed after starting treatment (Badenoch and Callender, 1960; Anand *et al.*, 1977) and the absorption of haemoglobin iron, in particular, does not depend on the integrity of the mucosa of the proximal small bowel and is not reduced even in untreated patients (Webb *et al.*, 1967; Anand *et al.*, 1977).

We studied the role of intestinal loss of iron in a group of children with coeliac disease on long-term treatment with gluten-free diet, with or without evidence of active disease. This was done to obtain information on the pathogenic mechanism of iron deficiency and on the indications for treatment with iron.

Subjects

A group of 24 children (13 boys and 11 girls) with coeliac disease were re-evaluated. The initial diagnosis had been based on the presence of a flat proximal jejunal mucosa between 9 months and 10·7 years before the study (Interlaken agreement; Visakorpi, 1970). The patients had been treated by excluding gluten from their diet and were being followed up at least annually at this hospital. During this time, most of the patients had been given courses of iron when they were found to be anaemic. At the time of the study the children were aged between 3 and 17·2 years.

Methods

Hb and RBC indices were measured by a Model S Coulter Counter from venous blood drawn into EDTA. Reticulocytes were counted microscopically. A blood sample was also drawn in the morning for serum analyses. Serum iron and total iron-binding capacity were determined spectrophotometrically in duplicate (Bothwell *et al.*, 1972; Rice and Fenner, 1974) and transferrin iron saturation was calculated. Storage iron was estimated by serum ferritin assay in triplicate (Siimes *et al.*, 1974).

The patients with transferrin saturation $<16\%$

Children's Hospital, Helsinki, Finland

and/or serum ferritin <1 μg/100 ml were started on treatment with iron; 2 mg ferrous iron/kg daily, given 1 to 2 hours before the meal. After a period of about 3 months the blood tests were repeated.

In 19 patients intestinal loss of iron was estimated by means of a 5-day stool collection 2 days after IV administration of 100 nCi ^{59}Fe Cl_3. The stools were then counted in a whole body counter with four detectors at 90° angles. The accuracy of the counting was ±20% in the activities of < 0·5 nCi, ±10% and ±7% in the activities of 1 and 2 nCi respectively. There are no control values from healthy children to indicate the physiological loss of iron by this technique. However, we have studied several children with severe iron deficiency anaemia and with suspicion of intestinal blood loss and found that presumed healthy children usually have <0·2 nCi (% of the injected label/5 days) in their stools. An arbitrary value of 0·5 nCi was used in this study as an upper limit of normal, although this value may be slightly too high.

In 5 additional patients daily stools were collected for between 7 and 10 days and analysed separately after giving the same dose of ^{59}Fe. The results of these counts were more accurate as there was only one stool container each day per measurement. The lowest detectable level of radioactivity was about 0·04 nCi.

In all 24 patients biopsy specimens were obtained from the first loop of jejunum using a Crosby-Kugler capsule of paediatric size; these were fixed in formalin, then routinely embedded, sectioned at 7 μm, and stained with haematoxylin and eosin. The histological findings were graded as total villous atrophy, partial villous atrophy, slight villous changes, and normal.

In order to obtain an additional and more sensitive quantitative criterion of the activity of the disease, the intraepithelial lymphocytes were counted in an area of the slide where the tissue was orientated, so that the plane of the section passed vertically through the epithelium and the basement membrane was easily visible. For each specimen at least 500 cell nuclei were counted. The results were expressed as the number of lymphocytes per 100 villous cells (Ferguson *et al.*, 1976).

The patients participated in this investigation voluntarily. The dose of radioactivity used was in accordance with the Scandinavian regulations on paediatric research (Radiation Protection Institutes in Denmark, Finland, Iceland, Norway, and Sweden, 1976)—i.e. a dose of less than the annual endogenous exposure.

Results

There was evidence of mild iron deficiency in the group of 24 children with coeliac disease. Hb, transferrin saturation, MCV of red blood cells, and serum ferritin were below the lower limits of normal in 6, 7, 6, and 8 patients respectively. However, anaemia was mild since the lowest Hb was 11·5 g/dl. The mean reticulocyte count was slightly raised. In 7 patients the values were above 1·5%, ranging from 1·6 to 2·3%.

A total of 10 children were considered to have iron deficiency by meeting at least two criteria denoting an abnormality. These patients were started on iron treatment, and later the laboratory values were all normal except in 2 of the 10 patients in whom the concentration of serum ferrin remained < 1 μg/100 ml. The mean levels of Hb, transferrin saturation, and serum ferritin rose from 12·6 to 13·4 g/dl, from 18·8 to 40·5% (P<0·01), and from 1·2 to 1·5 μg/100 ml respectively.

In 19 patients the mean amount of radioactivity in the 5-day stool specimens was 1·0 nCi (1·0% of injected dose) ranging from 0·2 to 3·0 nCi. In 17 of them the value was considered abnormal: 0·5 nCi or more. The daily excretion of radioactivity was measured in 5 other patients. The results are shown in the Figure.

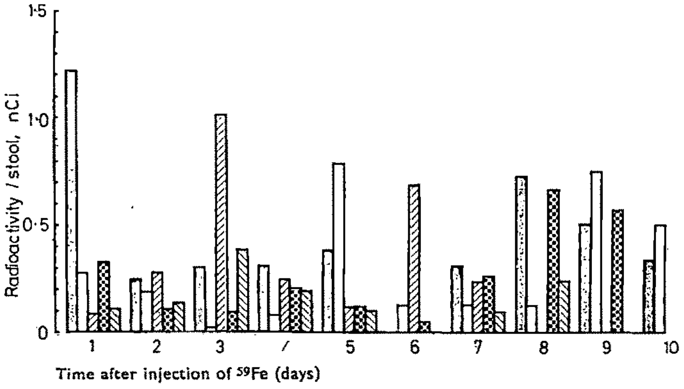

Figure *Radioactivity in stools of 5 patients collected daily after an intravenous injection of 100 nCi of* ^{59}*Fe* Cl_3*. Pattern of the secretion remained similar for 10 days, although there was a pronounced variation in individual stools from day to day. Each stool specimen contained some radioactivity. No specimen was obtained from 2 patients on day 6 and from some after 7 days.*

Abnormal proximal jejunal mucosa was found in 9 patients of whom 6 had total villous atrophy and 3 had only slight mucosal changes. The patients with flat mucosa had more radioactivity in their stools (from 1·2 to 3·0 nCi) than those with slight changes or normal mucosa (from 0·2 to 2·1 nCi).

In the patients with histological changes in mucosa the intraepithelial lymphocyte counts were high. The mean counts were 67, 55, and 32 and the total ranges from 51 to 87, from 44 to 64, and from 23 to 61 per 100 cells in patients with total villous atrophy, slight mucosal changes, and normal mucosa, respectively. The last range was also somewhat raised as in healthy individuals it is considered to be <34 (Kosnai and Kuitunen, 1977) or <38 lymphocytes/ 100 cells (Ferguson *et al.*, 1976). The intraepithelial lymphocyte count and the quantity of radioactivity in the stools showed a positive correlation in the 24 patients ($P<0·01$).

A negative correlation was found between the concentration of serum ferritin and the radioactivity in the stools ($P<0·001$).

Discussion

The results show a pronounced loss of radioactivity in stools after intravenous injection of labelled iron in a group of children with coeliac disease treated with gluten-free diet for at least one year. The loss could be attributed either to intestinal bleeding or to accelerated turnover of epithelial cells in which iron is lost in stools (Sutton *et al.*, 1970). Our results show that both mechanisms could be involved. However, the findings suggest that intestinal bleeding would account for a major proportion. The iron lost through epithelial cells should derive from serum and appear in stools during the first days after the injection, as the normally short turnover of these cells of about 3 days should be even more rapid in these patients. On the other hand, the incorporation of iron into haemoglobin starts immediately, and it is practically completed within 5 days. Accordingly, the radioactivity derived from red cells should gradually increase in the stools and then reach a certain plateau. It was evident that neither of these patterns was found. In addition, there seemed to be a pronounced variation in the loss of label from day to day in all patients.

The intestinal blood loss and signs of mild iron deficiency were greater in patients with total villous atrophy of the jejunum and in those with intraepithelial lymphocytosis. These findings suggest that iron treatment should be considered, for instance annually or semiannually, in these patients who are clearly unable to follow the dietary instructions. On the other hand, the patients who presumably kept to the diet more rigidly and who had a normal or almost normal mucosal histology also bled, although to a lesser extent. Some of these patients must therefore also have an increased need for iron, perhaps because some breaks in diet are inevitable even with strongly motivated families. Alternatively it is possible that subtle abnormalities in mucosal integrity remain, even with strict dietary management.

Several studies show that iron absorption is not a limiting factor in patients being treated for coeliac disease (Anand *et al.*, 1977). Our patients were able to compensate for most of the continuous loss of iron by increased absorption since any anaemia was mild. Patients with signs of iron deficiency responded well to iron, although they were unable to fill their iron stores as shown by the small change in concentration of serum ferritin (Siimes *et al.*, 1974). We feel that most children with coeliac disease require some iron. Reticulocytosis or reduced level of serum ferritin may be practical and sensitive criteria to detect these individuals.

Absorption of chlorhexidine from the intact skin of newborn infants

JENNIFER COWEN, STUART H. ELLIS, AND JAMES McAINSH

Department of Paediatrics and Neonatal Medicine, Hammersmith Hospital, London, and Imperial Chemical Industries Limited, Pharmaceuticals Division, Alderley Park, Macclesfield

SUMMARY 34 newborn infants who had been bathed in a standard manner with Hibiscrub* were studied to find out whether it was absorbed percutaneously. Low levels of chlorhexidine were found in the blood of all 10 babies sampled by heel prick, and 5 of 24 from whom venous blood was taken. The detection of chlorhexidine varied greatly with the method and timing of sampling, and no correlation was found between gestational or postnatal age and chlorhexidine levels.

Antiseptic substances have been applied to the skin and umbilical cord stumps of newborn babies for many years with a view to controlling bacterial colonisation and reducing the prevalence of neonatal infection (Farquarson *et al.*, 1952; Williams and Oliver, 1969; Evans *et al.*, 1970; Gezon *et al.*, 1973; Dankert *et al.*, 1977; Fares *et al.*, 1977; Wald *et al.*, 1977). Hexachlorophane, a phenolic derivative effective against Gram-positive organisms, has been the most widely used. This substance is now known to be absorbed through the intact skin, particularly in preterm infants (Curley *et al.*, 1971; Powell *et al.*, 1973; Tyrala *et al.*, 1977). It has also been recovered from the brains of such babies, where it has been associated with a spongioform myelinopathy (Powell *et al.*, 1973; Shuman *et al.*, 1974, 1975). This has led to restriction in its use, particularly in infants of very low birthweights. Chlorhexidine, effective against Gram-positive and some Gram-negative bacteria (Lowbury *et al.*, 1964, 1974), appeared to be an appropriate substitute. It is not absorbed in any significant amounts from the hands of adults, even after prolonged use (Case *et al.*, 1976). As the skin of immature infants is known to be unusually permeable, this study was undertaken to determine the extent, if any, of chlorhexidine absorption.

Patients and methods

34 infants nursed in the neonatal intensive care unit at Hammersmith Hospital between November 1974 and January 1977 were studied. The purpose and nature of the investigation was explained to their mothers, who agreed to their infants' inclusion; the study also had the sanction of the hospital's ethical committee.

All babies in the study were 'topped and tailed' using water alone until the umbilical cord separated. They were then (or when size and general condition permitted) bathed daily with Hibiscrub used in a standard way throughout. A small quantity of the substance was applied with the bather's hand to the baby's head, excluding the face, and washed off with plain water. Chlorhexidine was then applied to the rest of the body, excluding any areas of broken skin; the infant was next immersed up to his neck in a bath of plain water, and then dried.

Blood samples were taken by heel prick or from a vein on the back of the hand (see below). The sampling site was swabbed with 70% isopropyl alcohol, mopped dry with sterile cotton swabs, reswabbed with isopropyl alcohol and allowed to dry. Blood was taken at the same time as samples needed for clinical purposes if possible. The whole blood sample was stored at 4°C until spun. Serum after separation was also stored at 4°C until analysed by gas-liquid chromatography after solvent extraction, acid hydrolysis, diazotisation, and iodination. A straight line was fitted to each set of calibration data by the method of least squares. Estimates for the unknown concentrations, together with their 95% confidence limits, were made by direct calculation from this fitted line. All esti-

*Hibiscrub is a detergent-based preparation containing 4% Hibitane chlorhexidine gluconate. Hibiscrub and Hibitane are trade marks, the property of Imperial Chemical Industries Limited.

mated concentrations which gave negative values, or whose 95% confidence limits included zero, were considered as being not statistically significantly different from values obtained from blank samples. The numerical values, however, are included for completeness.

The gestational ages of the infants were calculated using the mothers' last menstrual periods and checked by a neurological and morphological scoring method (Dubowitz *et al.*, 1970). The 34 infants were divided into three groups.

Group 1 (10 infants). Blood samples were taken by heel prick at varying times after the first bath. Details of sexes, birthweights, gestational and postnatal ages are shown in Table 1.

Group 2 (7 infants). Samples were taken by venepuncture 4 hours after the first bath in case any measurable chlorhexidine in group 1 infants merely reflected adsorption of chlorhexidine on to the skin. Clinical details are shown in Table 2.

Group 3 (17 infants). Venous samples were withdrawn 12 hours after bathing and at weekly intervals if possible. These infants were studied to see if accumulation occurred and to attempt to see whether there was any correlation between gestational and postnatal ages and chlorhexidine blood levels. Details are shown in Table 3.

Results

Chlorhexidine was found in samples of blood taken from all 10 preterm infants in group 1 (Table 1). It was not realised, at this stage, that chlorhexidine is so strongly adsorbed on to the skin surface that it was not removed by the alcohol wash, so these results were almost certainly due to contamination of the sample by residual chlorhexidine on the skin. Where the concentrations were estimated as being negative these are shown as zero in the table.

Unlike the heel prick results, those recorded in venous samples were near the limits of detection of the assay and, therefore, some of the positive values could have been due to chance. Those that are considered to be significantly different from zero, based on the 95% confidence limits, are marked with an asterisk in the Tables and will be referred to as being significant in the following remarks.

While venous samples from infants in group 2 appeared positive in 6 of the 7 babies (Table 2), the three 'significant' values in this group were recorded in the 3 babies of 36 weeks or less. The infant who had no detectable chlorhexidine (Case 16) had an identical twin (Case 15) in whom 63 ng/ml was reported but, as this result does not differ significantly from zero, the 2 may have behaved identically with respect to absorption. The concentration of 460 ng/ml in Case 13 was very much higher than that in

the others in the group for no obvious reason. Postnatal age did not appear to affect the results.

When the results from the 17 infants from group 3 were analysed, only 2 significant positives were found. The percentage of significant positives was thus reduced from 95% in group 1, to 50% in group 2, and 5% in group 3. This would tend to confirm that at least some of the results in group 1 were owing to topical contamination with chlorhexidine. However, the only difference between group 2 (7 babies) and group 3 (17 babies) was that the samples were taken 4 hours after bathing in group 2 and 12 hours in group 3. It was not possible to detect any correlation between gestational–postnatal age and chlorhexidine levels in these groups, nor was there any tendency to accumulate the substance.

No unusual effects which could be attributed to chlorhexidine absorption were noted.

Discussion

This study was undertaken to ascertain whether chlorhexidine was absorbed through the intact skin of the newborn. It was prompted because hexachlorophane was in use as a bacteriostatic agent for more than 20 years before it was found to be absorbed (Curley *et al.*, 1971), and to be associated with spongioform lesions in the brains of monkeys and preterm babies bathed in it (Hart, 1971, cited by Lockhart, 1972; Powell *et al.*, 1973). The studies on hexachlorophane which led to these conclusions were undertaken when it was proposed to use hexachlorophane as a fungicide on fruit and vegetables.

The results reported from our survey show that chlorhexidine is detectable in the blood of some preterm and term infants after whole body bathing. Although there were more positive results in preterm babies, these were too few for statistical analysis. Percutaneous chlorhexidine absorption would not be surprising as many other substances are absorbed in this way, particularly in the neonatal period. These include hydrocortisone, trichlorocarbanilide, pentachlorophenol, and, of course, hexachlorophane (Fisch *et al.*, 1963; Feinblatt *et al.*, 1966; Armstrong *et al.*, 1969; Robson *et al.*, 1969). Nachman and Esterly (1971) demonstrated skin blanching with phenylephrine hydrochloride 10% in preterm but not term babies, thus confirming increased permeability in the immature. As any substance to which newborn skin is exposed may be absorbed to some extent it is a question of balancing its value against potential risks. There are differing views on the effectiveness of, or even the necessity for, topically applied antibacterial substances in newborn babies (Forfar *et al.*, 1968; Evans *et al.*, 1970; Gezon *et al.*, 1973; Light and Sutherland, 1973; American Academy of Pediatrics Committee on Fetus and Newborn, 1974; *British Medical Journal*, 1977; Dankert *et al.*, 1977), but it is beyond the scope of this paper to review opinions on this controversial subject.

There are no reports yet of any tissue toxicity due to chlorhexidine, but necropsy studies have not been made. Despite the extensive use of chlorhexidine in obstetrics, ear, nose, and throat surgery, in dentistry, and as a preoperative disinfectant, the only adverse reactions reported in adults have been associated with direct instillation into the middle ear, where in common with other antiseptics, it causes deafness. However, adults absorb virtually no chlorhexidine from the skin, even after prolonged use (Winrow *et* *al.*, 1973). Newborn rhesus monkeys bathed daily with chlorhexidine digluconate showed no clinical evidence of toxicity (Case *et al.*, 1976). Rats given chlorhexidine in their drinking water for 2 years showed no ill effects in life or at necropsy although there were easily detectable levels of chlorhexidine in the liver and kidney (Case *et al.*, 1976). It has been shown to cause concentration-dependent precipitation of rat liver microsomal protein, probably due to RNA binding and possibly to membrane binding too; and it binds rat liver microsomes affecting various enzyme systems in them (Christensen and Jensen, 1974; Christensen *et al.*, 1975). These effects were noted on subcellular fractions exposed directly to high concentrations of chlorhexidine, and all were thought to be related to the cationic amphipathic nature of chlorhexidine. Pharmacologically chlorhexidine is a biguanide, and the related substances phenformin and metoformin exert their metabolic effects by inhibiting fatty acid oxidation at toxic doses; they also inhibit oxidative phosphorylation (Muntoni, 1974).

With regard to the prime object of this study which was to demonstrate whether chlorhexidine is absorbed from the skin of newborn infants, the possibility of its adsorption to skin makes interpretation of results from heel prick samples inconclusive. When blood was obtained by venepuncture, however, small amounts of chlorhexidine were found in the blood of a few babies tested. Some of the most immature infants in this study were several weeks old when first bathed with chlorhexidine, so their skin permeability would already be less than at birth. Should further work be undertaken, sampling technique and postnatal age at exposure must be taken into account, and the use of chlorhexidine in obstetric units remembered.

We thank Mr B. F. Holmes, ICI, for analysis of chlorhexidine blood samples, Miss Castle and her staff of the premature baby unit, Hammersmith Hospital, for their help, and Dr Pamela Davies for encouragement.

Infective pericarditis in Nigerian children

F. JAIYESIMI, A. A. ABIOYE, AND A. U. ANTIA

University College Hospital, Ibadan, Nigeria

SUMMARY 53 children with infective pericarditis were seen at the University College Hospital, Ibadan, between 1967 and 1976. Their ages ranged from 10 days to 15 years but 53% of them were aged 5 years and below. Cough, fever, and breathlessness were the most common symptoms; cardiac decompensation was evident in over 30% of them, 23% had muffled heart sounds, but a pericardial friction rub was audible in only one. The main pathogens identified were *Mycobacterium tuberculosis* (11 cases), *Staphylococcus aureus* (11 cases), *Escherichia coli* (4 cases), *Pneumococcus* and *Pseudomonas* (3 cases each). Most of the patients had some other associated infection—such as, bronchopneumonia (12 cases), empyema thoracis (10 cases), lung abscess (10 cases), septicaemia (6 cases), and osteomyelitis (3 cases). Errors in diagnosis were common, the diagnosis having been missed in 72% of the cases identified at necropsy. Even if the correct diagnosis had been made during life and appropriate treatment given, the mortality rate (36%) was high. It is suggested that the onset of cardiac failure in any child with bronchopneumonia, empyema, or lung abscess should always arouse a suspicion of infective pericarditis.

Studies by many workers from developed countries on infective pericarditis suggest that this disorder is a rarity in childhood (Horan, 1957; Boyle *et al.*, 1961; Nadas and Levy, 1961; Benzing and Kaplan, 1963; Gersony and McCracken, 1967; D'Cruz *et al.*, 1970; van Reken *et al.*, 1974). Few studies on pericardial diseases have been undertaken by workers from the developing countries and these have concerned mainly adults (Schrire, 1964; Brockington and Edington, 1972; Carlisle and Ogunlesi, 1972; Brockington, 1974; Odi Assamoi *et al.*, 1975). To our knowledge there has been one study on pericardial diseases from Africa on children and adults and this suggested that infective pericarditis is more common among children in the developing countries than in developed ones (D'Arbella *et al.*, 1972). The purpose of the present study is to document the prevalence, clinical features, aetiological factors, and prognosis of infective pericarditis seen at the University College Hospital, Ibadan, during a period of 10 years.

Materials and methods

The study was prospective as well as retrospective. The prospective aspect comprised 14 children with infective pericarditis referred to the paediatric cardiac unit between January 1967 and December 1976. Clinical diagnosis of infective pericarditis in 11 of the 14 patients was confirmed by diagnostic pericardiocentesis which in each case yielded pus. The pericarditis in the remaining 3 children was of tuberculous origin, as confirmed by the pericardial exudate, a strongly positive tuberculin test, and satisfactory response to treatment with anti-tuberculous drugs. All 14 children underwent detailed evaluations, and their nutritional states were assessed from their weights, heights, mental states, muscle mass, subcutaneous tissues, and skin changes. Investigations carried out on each child were: blood count, haemoglobin genotype, culture of blood, pericardial or pleural aspirates, electrocardiography (ECG), and chest radiography. One patient underwent venous angiocardiography.

The retrospective study comprised 39 cases identified at necropsy during the same 10-year period. The necropsy diagnosis of these 39 cases was based on widely accepted criteria (Scotti, 1971). The clinical, laboratory, and necropsy findings of these patients were also reviewed.

Cases of pericarditis associated with cardiothoracic

University College Hospital, Ibadan, Nigeria
Department of Paediatrics
F. JAIYESIMI, senior lecturer and consultant paediatric cardiologist
A. U. ANTIA, professor and consultant paediatric cardiologist
Department of Pathology
A. A. ABIOYE, professor and consultant pathologist

surgery, uraemia, malignancies, collagen disorders, endomyocardial fibrosis, or idiopathic cardiomegaly were excluded from the study. It should also be emphasised that the present series may not represent all the cases of infective pericarditis that passed through the hospital during the period as some of the patients might not have come to our attention.

Results

There were 53 patients (28 boys and 25 girls) and their ages ranged from 10 days to 15 years (mean 5·3 years). Two (4%) of them were neonates, 26 (49%) were between 1 month and 5 years, 16 (30%) between 6 and 10 years, and 9 (17%) were aged between 11 and 15 years.

Symptoms and signs. The commonest presenting symptoms were fever, cough, and breathlessness (Table 1). Five of the older children complained of retrosternal chest pain while 3 others, all aged less than 5 years, had febrile convulsions. Cardiac decompensation, as evidenced by tachycardia, weak peripheral pulses, raised jugular venous pressure, gallop rhythm, or hepatomegaly was present in over 30% of the children. Less than 25% of patients had muffled heart sounds, and pericardial friction rub was present in one. Kussmaul's sign was demonstrable in only one patient.

Nutritional state. Complete data on the nutritional state were available in 37 (70%) of the 53 patients. 10 (27%) of these 37 patients were marasmic while the remaining 27 (73%) were well nourished.

Chest radiography. Enlargement of the cardiac silhouette was present in 22 (82%) out of 27 patients in whom the cardiac borders were clearly discernible. Three of these 22 patients with enlarged cardiac silhouettes had constrictive pericarditis of tuberculous origin. In one of the 22 patients pericardiocentesis yielded very little purulent aspirate in spite of clinical, radiological, and ECG signs of a large pericardial effusion. In order to assess the amount of the effusion a jugular venous angiocardiogram was carried out and it showed a large amount of pericardial fluid (Fig. 1). Another interesting chest *x*-ray which posed some diagnostic problem was that of an 11-month-old girl who presented with a history of fever, cough, breathlessness, and a swelling in the neck. On examination she was pyrexic (39°C) and had signs of cardiac failure and a left pleural effusion. In addition she had a tender and fluctuant mass which seemed to arise from the thoracic inlet. Although the mass did not move with swallowing, it increased in size whenever the child cried. The chest *x*-ray showed a large globular heart and a wide superior mediastinal shadow (Fig. 2). Diagnostic paracentesis of the left pleural cavity, pericardial space, and the cervical mass yielded pus. Post-paracentesis chest *x*-ray showed pneumonediastinum with the air extending into the soft tissue in the neck.

Table 1 *Symptoms and signs in 53 children with infective pericarditis*

Symptoms	*No. of patients*	*% of total*	*Signs*	*No. of patients*	*% of total*
Fever	39	74	Pyrexia	53	100
Cough	35	66	Tachycardia	45	85
Breathlessness	28	53	Dyspnoea	36	68
Abdominal swelling	12	23	Hepatomegaly	35	66
Swelling of legs	12	23	Weak peripheral pulses	21	40
Anorexia	7	13	Pulmonary crepitations	21	40
			Splenomegaly	20	38
Swelling of face	6	11	Peripheral oedema	19	36
Vomiting	6	11	Mucosal pallor	19	36
Chest pain	5	9	Raised jugular venous pressure	18	34
Diarrhoea	4	8	Muffled heart sounds	12	23
Vomiting	4	8	Ascites	10	19
Convulsions	3	6	Gallop rhythm	6	11

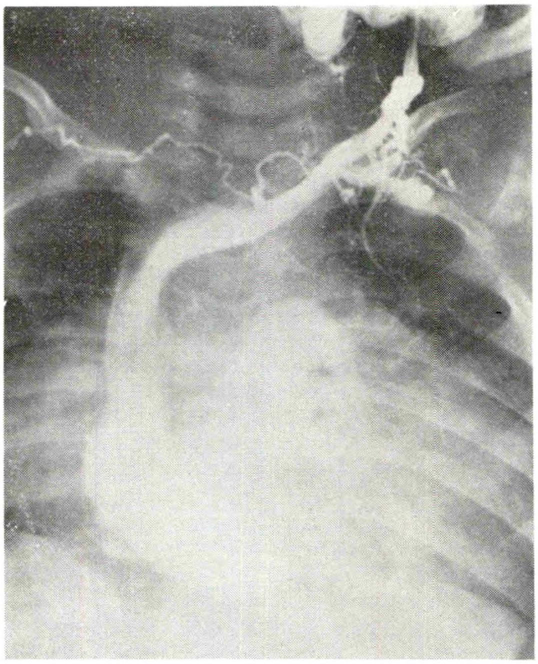

Fig. 1 *Percutaneous venous angiocardiogram of a baby with purulent pericarditis. The pericardial effusion is demarcated on the right side by the opacified right atrium and the outer border of the cardiac silhouette.*

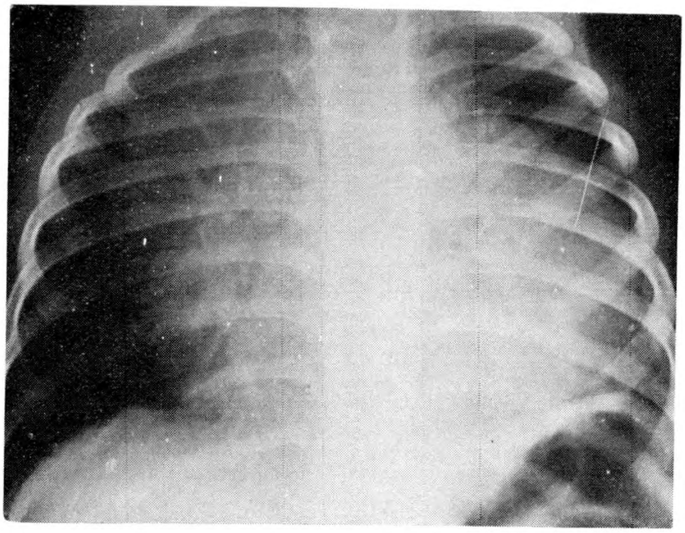

Fig. 2 *Chest x-ray of an 11-month-old child with pyopericardium and pyomediastinum. Note the soft-tissue shadow in the superior mediastinum.*

It was thus concluded that the cervical abscess was an extension of a large pyomediastinum. Satisfactory recovery followed drainage of the pus collections and administration of erythromycin, digoxin, and hydroflumethiazide.

Other radiographic findings were bronchopneumonic consolidation (12 cases) and pleural effusion (10 cases). The pleural effusion was on the left side in 7 patients, on the right in 2 others, and bilateral in one. Pericardial calcification was evident in one patient with purulent pericarditis.

Electrocardiographic findings. Electrocardiograms were obtained in all 14 patients studied prospectively and in one of the necropsy cases. Flat or inverted T-waves, the commonest abnormalities, were observed in 10 (67%) of the 15 patients while 7 (47%) patients had dwarfed QRS complexes. Other ECG abnormalities included S-T depression (4 cases), bifid P-waves (2 cases), and frequent but unifocal ventricular premature contractions (1 case).

Aetiological agents. Aetiological agents were identified on Gram-stain and cultures either of the aspirates or blood in 31 (58%) of the 53 patients. The commonest nontuberculous pathogens were *Staphylococcus aureus*, *Escherichia coli*, *Pneumococcus*, and *Pseudomonas aeroginosa* (Table 2). These organisms were isolated from the blood (6 patients), pericardial aspirates (9 patients), and pleural aspirates (4 patients). Three of the 4 patients with *E. coli* pericarditis were aged less than one year. Eight patients had histological evidence of tuberculosis in pericardial specimens obtained at necropsy while in 3 others the diagnosis of tuberculosis was made before death. Guinea-worm was identified in the pericardium of one patient at necropsy.

Table 2 *Aetiological agents*

Pathogen	*No. of cases** ($n=36$)	*% of all isolates*
S. aureus	11	31
M. tuberculosis†	11	31
E. coli	4	11
Pneumococcus	3	8
P. aeroginosa	3	8
Klebsiella sp.	2	5
Salmonella typhi	1	3
Dracunculus medinensis (guinea-worm)	1	3

*4 patients each had more than one pathogen: (i) *S. aureus*, *Pseudomonas*, and *Klebsiella*; (ii) *S. aureus* and *Pneumococcus*; (iii) *Pneumococcus* and *Klebsiella*; (iv) *E. coli* and *Pseudomonas*.
†Histological proof only.

Haematological findings. Total white blood counts were available in 19 patients, 14 (74%) of whom had a polymorphonuclear leucocytosis (neutrophils $>7{\cdot}0 \times 10^9/l$; 7000/mm^3). Anaemia (haematocrit $<25\%$) was present in 6 out of the 19 patients whose haematocrits were available. The haemoglobin genotype was determined in 21 patients; it was A in 18 patients, and A+S in 2 others. One patient had haemoglobin SC disease.

Associated conditions. 20 (38%) of the 53 patients either had empyema thoracis or an extensive lung abscess (Table 3). Five patients had both empyema and lung abscesses. The bronchopneumonia which was present in 12 patients was presumed to be bacterial in origin. Less common associated conditions were pyogenic meningitis, acute bacterial

Table 3 *Associated conditions*

Associated disease	*No. of cases*	%
Bronchopneumonia	12	23
Metastatic abscess (<2 cm in diameter)		
Lungs	7	
Brain	2	21
Kidney	2	
Empyema thoracis	10	19
Extensive lung abscess	10	19
Tuberculosis		
Pulmonary	4	
Meningeal	2	
Disseminated	2	17
Spinal	1	
Septicaemia	6	11
Osteomyelitis	3	6

endocarditis, myocardial abscess, omphalocele, congenital hydronephrosis, and left ventricular submitral aneurysm (one case of each).

Pathological types. 22 (42%) of the 53 patients had purulent pericarditis (Table 4); 13 of these 22 patients had some other intrathoracic suppurative lesions. Three patients with purulent pericarditis developed fatal cardiac tamponade, and at necropsy each of them had >300 ml pus in the pericardial cavity. 11 patients had serious pericarditis: 4 cases were tuberculous while the remaining 7 were idiopathic. Six of the 7 cases of contrictive pericarditis were also of tuberculous origin; the aetiology of the 7th case was unknown.

Antemortem diagnosis. Pericarditis was not suspected during life in 28 (72%) of the 39 cases identified from necropsy records; in most instances only the associated pulmonary infection was accurately diagnosed. Even when cardiac failure was recognised, as indeed was the case in 7 (25%) of the 28 cases, it was usually ascribed either to idiopathic cardiomyopathy or to acute cor pulmonale resulting from pneumonia or empyema.

Treatment and outcome. The 14 patients studied prospectively were managed with appropriate antibiotics, drainage of pus collections, digoxin, diuretics, and blood transfusion in appropriate cases. Five (36%) of the 14 patients died; 4 of them had purulent pericarditis and one had tuberculous pericarditis. Thus the mortality rates were 36 and 33% respectively for purulent and tuberculous pericarditis. Age, sex, nutritional state, or duration of the illness before hospitalisation did not appear to affect the mortality. In 2 of the 5 fatal cases there was an associated large lung abscess and a massive empyema in 2 others. The 9 survivors have been followed up for periods varying between 18 months and 4 years. Eight of them have recovered completely (Figs 3a, b) while the remaining patient has persistent cardiac decompensation.

Table 4 *Types of pericarditis in 53 children*

Type	*Patients* *(n=53)*	%
Fibrinoid pericarditis	5 (1)	9
Effusive		
Serous	11 (4)	21
Purulent	22	42
Haemorrhagic	3	6
Adhesive pericarditis	5	9
Constrictive pericarditis	7 (6)	13

Figures in parentheses denote proportion of cases that were of tuberculous origin.

Discussion

The present series of 53 cases of infective pericarditis seen during a period of 10 years in children aged 10 days to 15 years is in accord with the 62 cases reported from Uganda by D'Arbella *et al.* (1972) in patients aged 0–20 years. In contrast, Simcha and Taylor (1971) reported only 5 cases seen at The Hospital for Sick Children, London, between 1952 and 1970. Workers from different parts of North

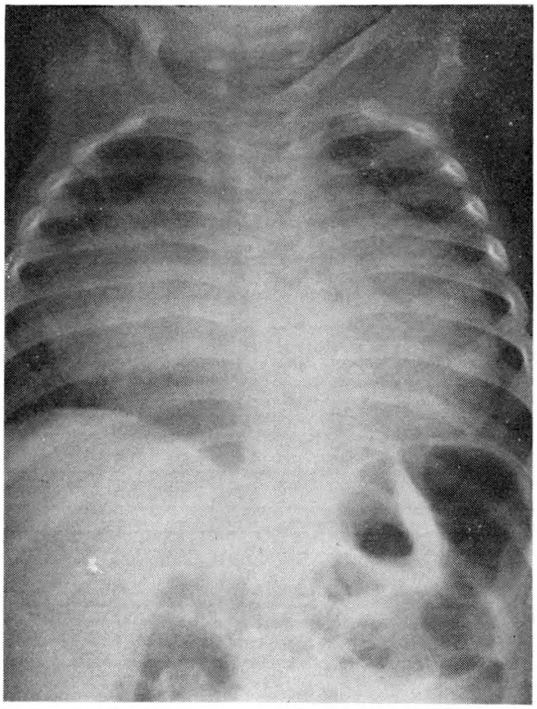

Fig. 3a *Chest x-ray of a baby with purulent pericarditis; the cardiac silhoutte is enlarged and globular.*

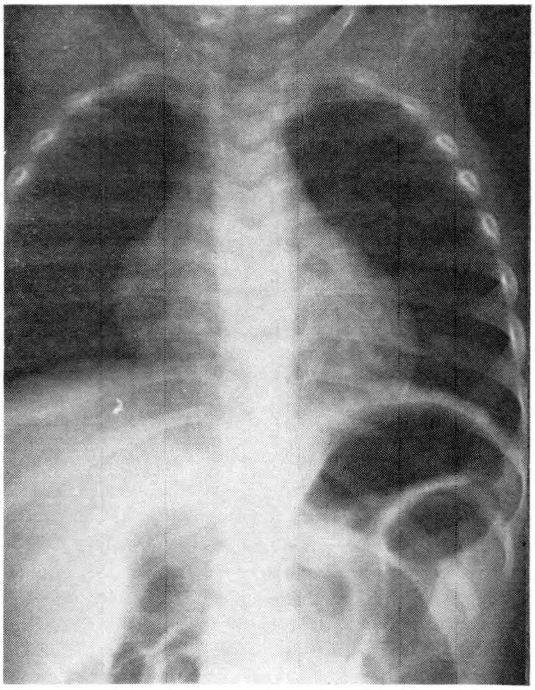

Fig. 3b *Same patient as in Fig. 3a, 4 weeks later. The cardiac size had returned to normal after pericardial drainage and administration of antibiotics, digoxin, and diuretics.*

America (Benzing and Kaplan, 1963; van Reken *et al.*, 1974; Strauss *et al.*, 1975; F. Jaiyesimi, unpublished data) have also stressed the rarity of infective pericarditis in childhood in these developed countries. It may thus be concluded from the present series, and that of D'Arbella *et al.* (1972) from Uganda, that infective pericarditis is a more common childhood disease in the developing countries than in developed ones. Poor sanitation, widespread malnutrition with its depressing effects on immune mechanisms (Chandra, 1972; Dossetor *et al.*, 1977), and the high incidence of bacterial respiratory infections (Abdel-Khalik *et al.*, 1938; Mimica *et al.*, 1971; Aderele, 1977; Silverman *et al.*, 1977), no doubt contribute to the high prevalence of infective pericarditis in children living in developing countries; but infective pericarditis is by no means a major childhood health problem in such countries. For example, it accounted for only 6% of paediatric cardiac disorders (A. U. Antia and F. Jaiyesimi, unpublished data), and for less than 1% of total paediatric admissions into University College Hospital, Ibadan, during this 10-year period. Similarly, during the same period 2079 necropsies were carried out on children aged 15 years and below, and the incidence of infective pericarditis was 0·02%.

In the present as well as in other series (Horan, 1957; Al-Omari and Samarrai, 1971; D'Arbella *et al.*, 1972; van Reken *et al.*, 1974; Odi Assamoi *et al.*, 1975) *S. aureus* was the most common aetiological agent. This organism has also been reported to be the commonest infectious agent in other conditions in our hospital (Aderele *et al.*, 1974; Montefiore *et al.*, 1974; Jaiyesimi, 1977). *E. coli* was the next most common pyogenic organism and this may be related to the number of infants in the present series. It is worth noting that the aetiological agent was unknown in 41% of the patients in the present study. D'Arbella *et al.* (1972) also reported a high incidence of idiopathic cases in their series. This high incidence of idiopathic cases may be attributed to several factors. Firstly, antibiotics might have been administered before the patients' admission into hospital. Secondly, a low index of suspicion would result in many cases being unrecognised and thus in failure to institute appropriate investigations. Thirdly, in most of our patients no virological studies were carried out.

Several workers have stressed the ease with which cases of infective pericarditis are unrecognised before death (Poynton, 1908; Poynton, 1934; Horan, 1957; Boyle *et al.*, 1961). In the present series the diagnosis was missed in 72% of cases that came to necropsy. This high incidence of misdiagnosis may be due to the nonspecific nature of the presenting symptoms and the scarcity of characteristic signs. For instance, a pericardial rub is audible in only 15 to 25% of cases (Benzing and Kaplan, 1963), while the intensity of the cardiac sounds may be normal in the presence of cardiac tamponade (Williams and Soutter, 1954; Nadas and Fyler, 1972). Occasionally some of the characteristic signs may be obscured by those of a coexisting bronchopneumonia, lung abscess, or empyema, as was indeed the case in most of our patients. Similarly, the clinical diagnosis of effusive tuberculous pericarditis is fraught with pitfalls: the same globular, 'murmurless' heart may be due to endomyocardial fibrosis and the pericardial fluid chemistry may be similar in both endomyocardial fibrosis and tuberculous pericarditis (Antia, 1968; Somers *et al.*, 1971). In such clinical situations a right ventriculography may be the only method of differentiating between these two conditions.

The spectrum of associated conditions in the present series is similar to that described by previous authors (Boyle *et al.*, 1961; Benzing and Kaplan, 1963; van Reken *et al.*, 1974). However, the extensive pyomediastinum which was found in one patient has not, to our knowledge, been previously reported.

The factors which have been reported to have adverse effects on the prognosis in purulent pericarditis are overwhelming infection (Horan, 1957), and inadequate evacuation of the pus within the pericardial cavity (Al-Omari and Samarrai, 1971). In the present series prognosis appeared to have been adversely affected by septicaemia, coexisting suppurative lung disease, and misdiagnosis with failure to institute appropriate treatment. Rooney *et al.* (1970) suggested that prognosis in tuberculous pericarditis might be adversely affected by delay in diagnosis and treatment, as well as by the mechanical constraints which pericardial inflammation imposes on myocardial compliance. As only 3 of our prospectively-studied patients had tuberculous pericarditis we cannot make any valid statements on the prognosis in that category of patients.

The failure to recognise many cases of infective pericarditis before death highlights the need for a high index of suspicion on the part of clinicians, particularly those who practise in the developing countries where the disease is relatively more common. The onset of cardiac failure in any child with bronchopneumonia, empyema, or lung abscess should always arouse a suspicion of purulent pericarditis. In addition to frequent clinical and radiographic evaluations, a diagnostic pericardial tap should be mandatory in all such patients; and a venous angiocardiogram may be required occasionally to demonstrate a loculated pericardial effusion. The need for these invasive procedures, however, can be obviated by echocardiography, this being a non-invasive and perhaps the most sensitive method of detecting pericardial effusions (Feigenbaum *et al.*, 1966; Moss and Bruhn, 1966; Feigenbaum, 1972; Meyer and Kaplan, 1972). Furthermore the ease with which echocardiography can be repeated renders it invaluable in assessing the course of a pericardial effusion.

Change of reference style

From January 1980, the *Archives* will change its style for citing references and will follow the number system. We are making this change in order to conform with the 'Vancouver style' of uniform requirements for manuscripts submitted to biomedical journals.

Previously the *Archives* has used the Harvard reference system. Its advantages and disadvantages compared with those of the number system have seemed evenly balanced, but the editors have been aware of the burden imposed on authors and their secretaries by the different styles which different journals require. Therefore, with the unanimous agreement of the editorial committee, we have decided to support a move whereby a large—and increasing—number of major medical journals will accept manuscripts presented in one agreed style.

The system numbers references consecutively in the order in which they are first mentioned in the text. References are identified in the text by arabic numerals. For further details see instructions to authors inside the front cover, and the references cited.[1,2]

From now onward all manuscripts submitted should accord with the new style.

Short reports

Comparison of IV salbutamol with IV aminophylline in the treatment of severe, acute asthma in childhood

G. HAMBLETON AND M. J. STONE

Park Hospital, Davyhulme, Manchester

SUMMARY A double-blind test to compare IV aminophylline with salbutamol in the treatment of acute, uncontrolled asthma showed that both drugs were equally effective during the first 24 hours. Salbutamol caused a relative tachycardia. Hydrocortisone was given after 2 hours, but did not appear to affect the rate of recovery.

A double-blind test was undertaken to compare aminophylline with salbutamol given intravenously to children admitted to hospital with acute, uncontrolled asthma. 18 children (12 boys and 6 girls) were studied, age range 1½ to 7 years. All were considered to be sufficiently ill to require intensive hospital treatment on clinical grounds. Blood-gases on admission were attempted in all children and obtained in 13. Of these, 12 showed hypoxaemia, 5 showed acidaemia, and one showed hypercapnoea. Using random number tables the children were allocated to receive double-blind either salbutamol 4 µg/kg immediately then 0·6 µg/kg per hour continuously for 24 hours or aminophylline 4 mg/kg immediately then 0·6 mg/kg per hour continuously for 24 hours. In 2 children the initial dose of bronchodilator was omitted because both of them had received bronchodilator treatment during the 4 hours before admission. After 2 hours all children received hydrocortisone 4 mg/kg immediately then 2 mg/kg per hour continuously for 22 hours. All patients were offered oxygen via face masks.

The study took place during the first 24 hours of admission. The children were assessed according to their clinical signs, pulse rates, and respiratory rates at 1, 2, 4, 6, 12, 18, and 24 hours. Clinical signs were

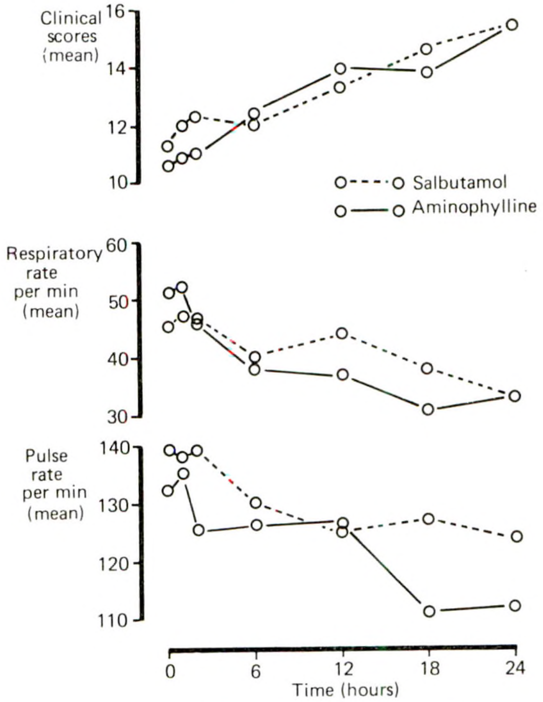

Figure *Mean values of pulse rates, respiratory rates, and clinical scores during first 24 hours.*

Table *Scoring system for signs*

	Score			
	4	*3*	*2*	*1*
Recession	Nil	Intercostal	Intercostal + suprasternal	Intercostal + suprasternal + lower costal
Tracheal tug	—	Nil	Present	Pronounced
Air entry	Normal	Reduced	Barely audible	Absent
Rales	—	Nil	Occasional	Widespread
Rhonchi	Nil	Scattered	Widespread, numerous	Concerted (= wheeze)

scored according to the method shown in the Table, a modification of the method used by Pierson *et al.* (1974).

Results

Pulses, respiratory rates, and clinical scores are shown in the Figure. No child showed any significant deterioration after starting treatment, and the condition of all children improved steadily after one or two hours. No statistically significant difference (Student's *t* test) between the aminophylline and salbutamol groups was found, except for pulse rates at 18 and 24 hours, when salbutamol appeared to cause a relative tachycardia.

Discussion

Clinical signs improved in all children from starting treatment, and pulse and respiratory rates improved after 2 hours. All children were unequivocally better at 6 hours. Their improvement during this period can be largely attributed to either salbutamol or aminophylline. Although the children received hydrocortisone after 2 hours, it is unlikely that this drug began to have any effect for several hours (Collins *et al.*, 1970, 1975). Furthermore our data give no indication that there is a precise time at which recovery is accelerated after the administration of hydrocortisone. The results are similar to those of Pierson *et al.* (1974) who carried out a study in which hydrocortisone appeared to ameliorate hypoxaemia immediately, but did not affect any other parameters in this way.

Salbutamol caused a tachycardia seen at 18 and 24 hours, but the clinical significance of this is trivial. No patient suffered any cardiac arrhythmia.

Adder bites in children

R. N. WILD

Southampton University Medical School

SUMMARY 16 children with adder bites were admitted to hospital in Southampton in the years 1969–77. Two children were severely poisoned; these 2, and a 3rd, fulfilled suggested criteria for antivenom administration but they recovered without it. Three children had no treatment, and 9 children no analgesia. Prolonged morbidity was not seen in these children. Careful observation in hospital was the most important factor in management, with early clinical improvement obviating the need for antivenom.

Children are less likely to suffer long-term morbidity after snake bites than adults, but can suffer no less severely from the immediate consequences of the venom. Experience in Southampton shows that snake bites to children are not uncommon, although Reid (1976) suggested they were rare. Controversy still exists about the use of antivenom, particularly in children. The experience with children bitten by *Vipera berus*, and admitted to hospital in Southampton is reviewed.

Patients

A retrospective study was made of all children, aged 14 years or younger, admitted to hospital in Southampton with a diagnosis of adder bite during the 9 years 1969–77. The diagnosis was accepted if the observed signs were compatible, whether or not a snake was seen. Postdischarge morbidity was ascertained by writing to the families; most of the children were visitors to the area, making follow-up difficult.

During the period 1969–77, 16 children (14 of whom were boys) were diagnosed on clinical grounds as having suffered a snake bite (a snake was not seen in 2 cases), and admitted to hospital. They ranged in age from 14 months to 14 years. All but one incident occurred within the New Forest area of Hampshire in the months June, July, or August. The one exception was a boy who kept snakes for a hobby and was bitten at home in April (Case 15). Eight children were bitten on the leg or foot, 7 were bitten on the hand, and one on his ear as he lay in the grass.

Results

Details of the clinical findings and subsequent course are given in the Table.

Immediate effects. Pain from the infliction of the bite was the first symptom in most children, but one child complained initially of a painful, swollen foot (Case 9). The 14-month-old baby (Case 2) was alleged by his parents to have lost consciousness for 5 minutes shortly after the bite, but this may have been a breath-holding attack. Vomiting occurred in 4 children: in two within a few minutes (Cases 6 and 13), and in Cases 8 and 15 within 30 minutes of the bite.

Features on admission. Most of the children were seen in hospital within an hour of the bite, with the exception of Case 12 who sought help the next day. Those in whom envenomation had occurred displayed the characteristic signs as shown in the Table. Six children were thought to be only mildly poisoned, pain and swelling being slight. Another 5 were moderately severely poisoned, with swelling of the bitten limb. Only 2 were severely poisoned; the history of one is given below (Case 8).

It was thought envenomation did not occur in 3 children (Cases 2, 10, and 11), although characteristic fang marks were easily identifiable in each case. The following case reports illustrate the course of events in 2 children.

Case reports

Case 13. A 9-year-old girl vomited within minutes of being bitten on the right ankle. When seen in casualty department an hour later ankle oedema was noted. No systemic signs were noted; her BP was 90/65 mmHg. She needed pethidine to control severe pain. Within 2 hours bruising covered the

*All children received tetanus toxoid.

dorsum of the foot and ankle. Investigations showed a raised total white blood count ($17 \cdot 0 \times 10^9$/l); a slightly raised blood urea (8 mmol/l; 48·2 mg/100 ml); slight acidosis (HCO_3 20 mmol/l); a raised creatine phosphokinase (CPK 253 IU/l, normal <80 IU/l). She was treated with chlorpheniramine and penicillin V and the leg was kept in a raised position. 14 hours later oedema had spread to the thigh. Throughout, her BP remained stable. Her recovery was uneventful and she was discharged after 3 days.

Case 8. A 3½year-old boy became pale, lethargic, and vomited 30 minutes after being bitten on the right foot. When seen in hospital less than an hour later, the foot was oedematous. He was given hydrocortisone and transferred to Southampton. 90 minutes after the bite he was still pale and vomiting, with a recorded systolic BP of 50 mmHg. Bruising covered the foot, and inguinal nodes were already very tender. He was still hypotensive (45/20 mmHg) 4½ hours after the bite. Chlorpromazine was given to control vomiting, and chlorpheniramine for the rapidly developing oedema. Severe pain required pethidine initially, then pentazocine. Six hours after the bite his BP had returned to normal. At 16 hours swelling had reached the inguinal region. Thereafter his recovery was slow but uneventful, and he was discharged on the 8th day.

Treatment. All the children received tetanus toxoid; in 3 children this was the only medication. Pain was severe enough in 3 children to require narcotic analgesics, but 9 required no analgesia. The other drugs given are shown in the Table.

In no case was Zagreb antivenom used, although it has been available in Southampton since 1972.

Sequelae. All children made a complete recovery. The average length of stay in hospital was 3·4 days (range 1–9). Most children were virtually symptom-free at discharge, but Cases 13 and 14 were in discomfort for a further week, and Case 7 was lethargic for about 2 weeks.

Discussion

Experience gained by hospital admission of 16 children bitten by adders in one small area of the country during the last 9 years adds to our knowledge about their management. Although these 16 comprise all the children who presented at hospital in Southampton, it is not possible to comment on children who managed without medical help, or who presented at their local hospitals; one child in this series (Case 12) presented the day after being bitten.

In this series most of the children suffered no more than acute discomfort in a swollen, bruised limb. Three children were probably not poisoned; about 30% of snake bites fail to envenom (Henderson and Dujon, 1973).

In moderate poisoning it is likely that no treatment is required other than symptomatic therapy, usually analgesics and antiemetics. The use of antihistamines can be limited to those in whom angioneurotic-type oedema appears (Reid, 1976); it did not occur in the present series. Prednisone is of no value in the treatment of the more severe Malayan viper bite (Reid *et al.*, 1963).

Three children gave cause for anxiety (Cases 8, 13, and 15), particularly the 2 boys with hypotension. All 3 had early indications for the administration of Zagreb antivenom (Reid, 1976; D.A. Warrell, 1976, personal communication), but they recovered without it. Reid's indications include persistent or recurrent hypotension, a leucocytosis $>20 \cdot 0 \times 10^9$/l, metabolic acidosis, ECG changes, raised CPK values, and in adults, the presence of massive swelling within 2 hours of the bite. Warrell would also include neurological abnormalities, bleeding diatheses, and massive swelling within 4 to 6 hours, in children as well as adults.

Transient hypotension lasting 4 to 12 hours is common in severe venom poisoning: it lasted 6 hours in Case 8 and 5 in Case 15, and did not recur. Had the condition of either of them deteriorated or the hypotension persisted after 12 hours, antivenom would probably have been given. Case 13 had investigation abnormalities. From the criteria of Reid (1976), these indicated that antivenom should have been given, but as the patient was in a reasonably good clinical state, it was withheld pending further observation.

No child developed early massive swelling. Reid's reason for this being an indication for antivenom in adults is to reduce the period of morbidity, which can last several months. Prolonged morbidity is not a problem with children and these data confirm this. Warrell adds that early massive swelling indicates a large envenomation, and therefore an increased potential for cardiotoxicity; hence he includes children. This, however, he bases on his experience with puff-adders; it is not a reported problem with *Vipera berus*.

Conclusions

Some risk is inherent in many forms of treatment, particularly if the material is immunogenic. Zagreb antivenom, being a foreign protein, is in this category. Nevertheless it has been shown to combine efficacy with safety in monkeys (Theakston and

Reid, 1976), and there is no reason to believe it is less safe in humans. Antivenom has not yet been used in Southampton although 3 children might well have received it if the criteria (Reid, 1976; D. A. Warrell, 1976, personal communication) had been wholly accepted. However early clinical improvement showed that it was not necessary.

When there is a successful outcome one can accept that the clinical decisions were correct; the difficulty lies in deducing future management. Guidelines for the administration of Zagreb antivenom are reasonable, but if acted upon too early in children, may lead to unnecessary administration. In Southampton a policy of symptomatic treatment in hospital and careful observation has been safe. Zagreb antivenom remains available for the serious cases that do not show early improvement.

I thank Professor I. C. S. Normand, Dr M. Radford, and Dr C. F. Speirs for their advice and criticism.

Coeliac disease in identical twins

FRANCISCO JOSE PENNA, JOAQUIM ANTONIO CESAR MOTA,
MARIZA LEITAO VALADARES ROQUETE, ANFRISINA SALES TELES DE CARVALHO,
ANTONIO TARCISIO DE OLIVEIRA LEMOS, ALFREDO JOSE AFONSO BARBOSA,
ENNIO LEAO, ROBERTO ASSIS FERREIRA, AND LUIZ DE PAULA CASTRO

Paediatric Department, Federal University of Minas Gerais, Brazil

SUMMARY Coeliac disease occurred at the same age in MZ twins. The diagnosis was confirmed by histology of the small intestine, rapid response to a gluten-free diet, and relapse after reintroduction of gluten.

While the familial incidence of coeliac disease is incontestable, some workers emphasise the importance of inheritance (Anderson *et al.*, 1972; McNeish and Anderson, 1974), and others the environment (Hoffman *et al.*, 1966; Walker-Smith, 1973). We here report coeliac disease with identical age of onset in a pair of monozygotic twins. This is the only well documented report of concordant monozygotic twins with genetic study, apart from that of David and Ajdukiewicz (1975) which included one set of adult female twins who were 'probably monozygotic'.

Case reports

White twin boys were born at term, without complications, and with a single placenta. Twin 1 weighed 2·6

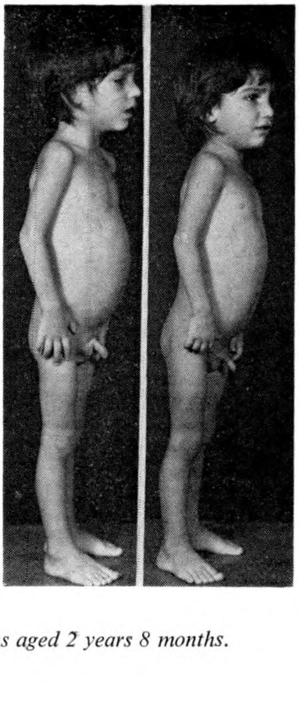

Fig. 1 *Twins aged 2 years 8 months.*

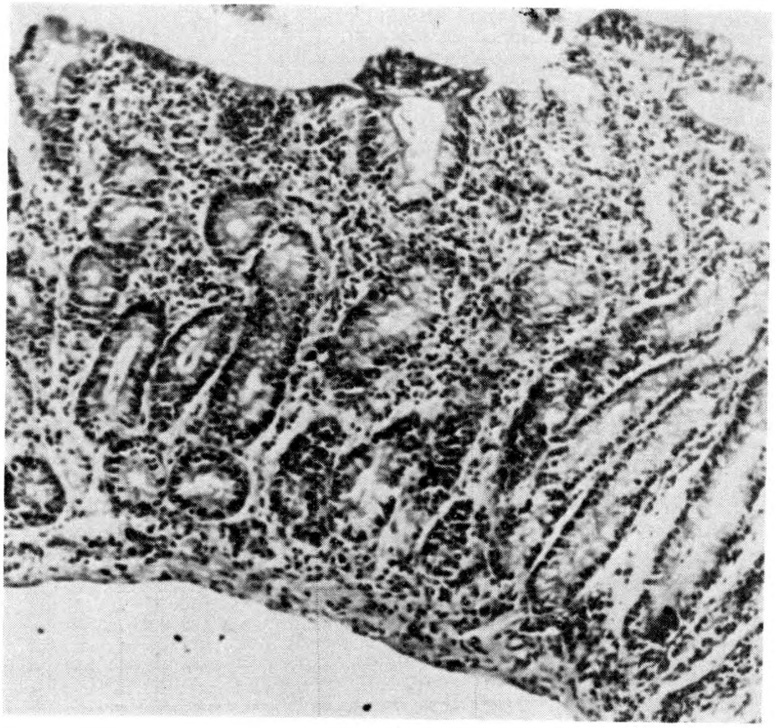
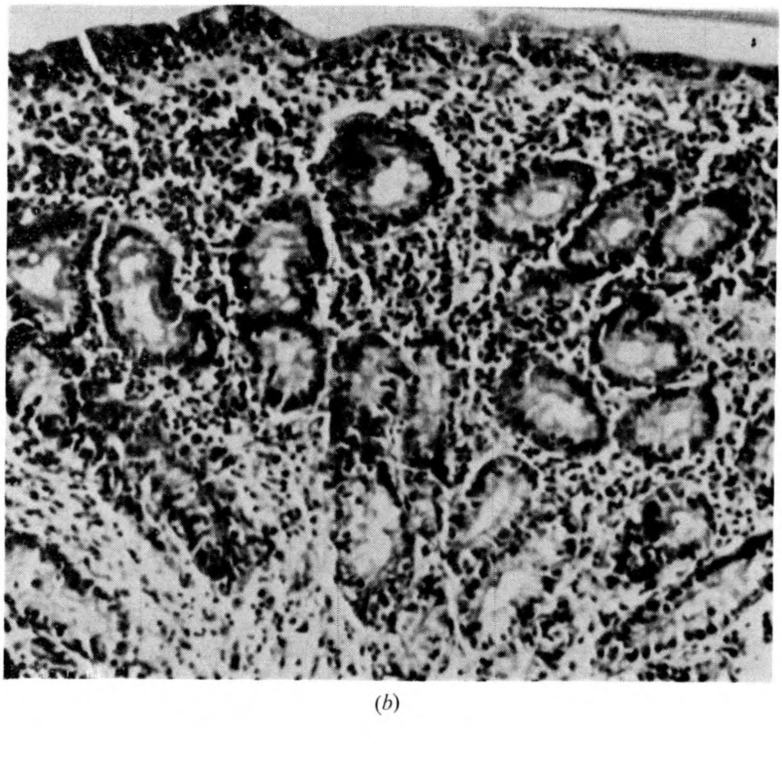


(*a*)



(*b*)

Fig. 2a, b *Jejunal histology of the twins.*

kg, twin 2 2·5 kg. Cows' milk was given from birth, and gluten-containing foods introduced at 4 months. They grew well until age 6 months, when both started to have episodes of diarrhoea with poor weight gains. At age of presentation, 2 years and 7 months, the stools were voluminous, yellowish, and shiny, were passed three times daily, and contained undigested food particles. Twin 1 then weighed 10·5 kg, length 88 cm; twin 2 weighed 10·4 kg, length 87 cm. Each was thin with protruding abdomen and wasted buttocks (Fig. 1). Small intestine biopsy was performed at the level of the duodenojejunal flexure, and in each was a typical mucosal pattern with absence of villi, cuboidal surface epithelium, hypertrophied crypts, and infiltration of the lamina propria by lymphocytes and plasma cells (Fig. 2).

Faecal fat excretion measured over a period of 72 hours gave 12·3 g/24h (43·3 mmol/24h) for twin 1 and 7·4 g/24h (26 mmol/24h) for twin 2.

Blood xylose after a loading dose (Roe and Rice, 1948) gave the following results: twin 1, 1st hour 26·2 mg/100 ml (1·7 mmol/l); 2nd hour 24·6 mg/100 ml (1·6 mmol/l). Twin 2, 1st hour 29·2 mg/100 ml (1·9 mmol/l); 2nd hour 24·6 mg/100 ml (1·6 mmol/l) (normal : 40 mg/100 ml ± 11).

MZ twin pregnancy was established by the following: (1) pregnancy with single placenta; (2) physical similarity of twins (Fig. 1); (3) dermatoglyphs. Unilateral comparison of the dermatoglyphic patterns of the left and right sides of the twins showed that the right hand of one twin was more like the right hand of the other, than was his own left hand. The total ridge count showed a difference of 8 between them. Holt (1961) reported that about 80% of MZ twins had differences of less than 20 ridges by total count, whereas only 30% of dizygotic twins had such small differences. (4) Blood groups. Both twins were A, D +, E −, $\bar{e}$ −, $\bar{c}$ +, C −, M +, N +.

Both parents and 2 brothers and 2 sisters were clinically normal, but it was not possible to carry out more extensive studies.

Both twins quickly responded to a gluten-free diet. After about 6 weeks the mother reintroduced a normal (gluten-containing diet) which was followed by severe clinical relapse. Since the reintroduction of a gluten-free diet, steady progress has been maintained to their present age (5 years). It was not possible to repeat the original biopsies.

Discussion

Monozygosity in the twins was based on the presence of a single placenta, similarity in physical appearance, and dermatoglyphic and blood group studies.

There are two reports in which only one of MZ twins was affected by the disease, indicating the possible involvement of environmental factors (Hoffman *et al.*, 1966; Walker-Smith, 1973). This occurred in one adult and one child pair respectively. McCrae (1969) suggested that a familial incidence, which may be as high as 44%, is evidence for the genetic basis of coeliac disease and he also emphasised the importance of environmental factors in the pathogenesis of the disease. David and Ajdukiewicz (1975), studying the familial incidence of coeliac disease, encountered 13 (9%) of 141 patients with a family history, and concluded that the disease could be transmitted by an incompletely penetrant autosomal dominant gene. The female preponderance noted in adult coeliacs was not evident in childhood coeliacs, with or without familial involvement.

We thank Professor Navantino Alves Filho for analyses of dermatoglyphs, Professor Marcos Borato Vianna for blood group determinations, and Dr Margot Shiner and Mr David Kingston for help with this paper.

Recurrent attack of rotavirus gastroenteritis after adenovirus-induced diarrhoea

S. CHIBA, R. KOGASAKA, M. AKIHARA, K. HORINO, AND T. NAKAO

Department of Paediatrics, Sapporo Medical College

SUMMARY A 14-month-old baby boy suffered a second attack of rotavirus gastroenteritis within one month of the initial one. The second attack followed a diarrhoeal episode associated with adenovirus. Gastrointestinal symptoms in the second attack were more severe than those of the first. The adenovirus-associated enteritis was mild compared with the illness in both episodes of rotavirus infection.

We report an infant in whom a second attack of rotavirus gastroenteritis occurred within a month. The second attack followed a diarrhoeal episode associated with type 7 adenovirus.

Case report

A 14-month-old baby boy was admitted on 8 February 1977 with typical acute gastroenteritis with diarrhoea, vomiting, anorexia, fever, and dehydration (Table). He received intravenous infusion and dietary treatment, and was discharged when completely recovered on 16 February. On 25 February he was brought to the outpatient clinic with a recurrence of diarrhoea. He had no vomiting or fever at that time and initially his condition improved but he continued to have loose stools. On 4 March he was readmitted with severe watery diarrhoea, frequent vomiting, and fever. Symptoms were more severe than those during the first admission; vomiting lasted for 5 days and diarrhoea for over a week. He was discharged when completely recovered on 19 March.

Laboratory data.

Electron microscopical examination

Stool specimens were consecutively collected and stored at − 70°C. The specimens were prepared for electron microscopy (EM) using the method of Flewett *et al.* (1974). Numerous rotavirus particles were found in the first and fourth stool specimens which were collected on 8 February and 4 March, but not in the other specimens. In the third specimen, collected on 25 February, a large quantity of adenovirus particles were found but no rotavirus ones. EM examination of the original specimens was

repeated with the same results. Bearing in mind the possibility that a small number of rotavirus particles might be present but not detectable, we also performed immune electron microscopical (IEM) examinations of the second and third specimens: the results were negative.

Culture

All fresh stool specimens were cultured for bacterial pathogens with negative results. Virus isolation was attempted using primary human embryonic kidney (HEK) cells. A cytopathic agent was recovered from the third stool specimen collected on 25 February. The cytopathic effect was typical of adenovirus, and EM observation of the culture fluid identified the isolate as adenovirus. The isolate was grown in HeLa cells and was identified as type 7 adenovirus.

Serology

Complement-fixing (CF) antibody titre was measured simultaneously against rotavirus and adenovirus antigens. The human rotavirus antigen was prepared by the method of Bishop *et al.* (1974) from the virus-rich stools of patients with acute gastroenteritis. Two adenovirus antigens were used; one was prepared from the isolated adenovirus strain and the other from commercially obtained type 3 antigen. CF antibody to rotavirus converted to positive after the first attack and further increased in titre until the last attack of gastroenteritis. Seroconversion to adenovirus antigens was also found during the second and last episodes of diarrhoea, with somewhat higher titres against the isolated virus. Neutralising antibody to the adenovirus isolate was also found to develop concurrently (see Table).

Discussion

This case may provide valuable information about viral gastroenteritis in view of the reinfection with rotavirus and the apparent pathogenic role of adenovirus in acute diarrhoea.

Although it has been assumed that reinfection with rotavirus could occur with second and subsequent episodes of gastroenteritis or in subclinical form, we are aware of only one patient who had a second episode of rotavirus enteritis (Davidson *et al.*, 1975). That patient, admitted with acute enteritis at 6 and again at 14 months of age, showed rotavirus particles in stools on both occasions. The interval between the attacks of rotavirus-induced gastroenteritis was shorter in our patient. As it is probable that $<10^5$ virus particules per ml would not be detected by routine EM examination, the technique of IEM was used to look for rotavirus during the intervening period. Even with the negative results of IEM, the possibility of an endogeneous reinfection still remained. In that case, adenovirus infection in the intestinal tract might have acted as a trigger for the second invasion of rotavirus. Recent studies have given evidence suggesting the existence of different serotypes among human rotavirus strains (Thouless *et al.*, 1978; Zissis and Lambert, 1978), so it may be possible for the same person to experience reinfection with a different antigenic strain of rotavirus. We could not examine the antigenic variation of rotaviruses recovered from the episodes of gastroenteritis, but it was interesting that gastrointestinal symptoms in the last episode were more severe than those of the first in spite of the pre-existing antibody.

In stools, apart from rotavirus, the second most common group of viruses easily recognisable by EM are adenoviruses (Bruce White and Stancliffe, 1975; Bryden *et al.*, 1975). We have observed adenoviruses in about 5% of all cases of gastroenteritis occurring in the winter (Kogasaka *et al.*, 1975). An aetiological role of such adenoviruses in gastroenteritis has long been controversial because of the lack of epidemiological evidence. The difficulty of growing in cell culture some adenoviruses which are visible by EM in great numbers contrasts with the easy propagation of some strains of adenoviruses undetectable by EM (Bryden *et al.*, 1975; Madeley *et al.*, 1977). We have used various cell cultures trying to grow adenoviruses visible by EM, and lately found HEK to be the only susceptible cells available in our laboratory. So far, we have grown 5 strains from 7 stool specimens found to be positive by EM, after a few blind passages in HEK (unpublished). One of those strains was recovered from the present patient and it enabled us to test for CF and neutralising antibody responses against the homologous strain. The results showed that primary infection with this type 7 adenovirus was present in the patient. The adenovirus was not just a passenger virus.

The adenovirus-associated enteritis in this case was remarkably mild compared with the illness in both episodes of rotavirus infection. Diarrhoea lasted only a few days and was not accompanied by vomiting. Flewett *et al.* (1975) reported an outbreak of adenovirus-associated diarrhoea in a long-stay children's ward. They mentioned the mildness of this type of enteritis in comparison with rotavirus enteritis experienced in the same ward. Thus acute enteritis associated with adenoviruses seems to be generally mild. Fatal adenovirus gastroenteritis described by Whitelaw *et al.* (1977) might be exceptional.

The present case emphasises the need to look for a different pathogen in repeated episodes of gastroenteritis.

Addendum

Since this paper was submitted recurrent gastroenteritis associated with different rotavirus serotypes has been reported by Fonteyne *et al.* (1978) and Rodriguez *et al.* (1978).

Pathogenesis of oxytocin-induced neonatal hyperbilirubinaemia

SUNIT SINGHI AND MEHARBAN SINGH

Department of Paediatrics, All-India Institute of Medical Sciences, New Delhi

SUMMARY 100 term (gestation at least 37 weeks), vertex presenting, vaginally delivered, and fetomaternal blood-group-compatible neonates were studied to evaluate the pathogenesis of neonatal hyperbilirubinaemia induced by oxytocin. 50 infants were born after oxytocin infusion for augmentation of labour and the other 50 were delivered spontaneously. The babies born after oxytocin induction of labour attained significantly higher serum bilirubin levels at age 72 ± 12 hours than the controls. Infants born after oxytocin showed significant hyponatraemia, hypo-osmolality, and enhanced osmotic fragility of erythrocytes at birth. These biochemical and physiological alterations can be explained by the antidiuretic effects of oxytocin and concomitant administration of large quantities of electrolyte-free dextrose solutions used to administer it. Our observations suggest that cord serum sodium and/or osmolality should be estimated and infants with serum sodium <125 mmol/l and/or osmolality <260 mmol/kg should be considered for prophylactic administration of phenobarbitone.

The role of oxytocin in causing neonatal hyperbilirubinaemia is now generally accepted (Oski, 1975; Chew and Swann, 1977). However, the pathogenesis of such a hyperbilirubinaemia is still a matter of speculation. A relatively immature glucuronyl transferase system due to absence of the hormonal upsurge of normal labour (Sims and Neligan, 1975) and an enhanced placento-fetal transfusion due to oxytocin-induced uterine contractions, with resultant increase in red cell mass in neonates (Oski, 1975), have been suggested. To explain the pathogenesis of oxytocin-induced neonatal hyperbilirubinaemia, we tested the antidiuretic effect of oxytocin.

Subjects and methods

From September to November 1977, 100 term (gestation at least 37 weeks), vertex presenting, vaginally delivered, fetomaternal blood-group-compatible neonates born at this hospital were studied. 50 of them were born after oxytocin infusion for induction or augmentation of labour (group 1), while the other 50 were delivered spontaneously (group 2). Oxytocin infusion in 5% dextrose was started at a rate of 2 mU/min (infusate oxytocin concentration of 4 U/l), increasing by 2 mU/min every half-hour, until effective uterine contractions were achieved. The duration of oxytocin administration varied between 4 and 24 hours. Serum bilirubin (Michaelsson's modification of Jendrassik-Grof-Nosseline method), serum sodium (by flame photometer), and serum osmolality (by Fiske osmometer), were estimated in the cord blood samples of all the infants. Serum bilirubin and sodium estimation was again done at postnatal age of 72 ± 12 hours. Saline osmotic fragility of cord blood erythrocytes was determined in 30 infants from each group. These infants did not differ significantly from the others. Phototherapy was withheld until the sample on day 3 was collected. None of the babies who developed early jaundice (<24 hours) or hyperbilirubinaemia (serum bilirubin >200 μmol/l; >11·7 mg/100 ml) had cephalhaematoma, G-6-PD deficiency, or an intrauterine infection. Statistical significance of differences in serum bilirubin, sodium, osmolality, and red cell osmotic fragility in the two groups was determined by Student's *t* test. The correlation coefficient was calculated between serum sodium and serum osmolality at birth, and serum bilirubin at 72 ± 12 hours of age.

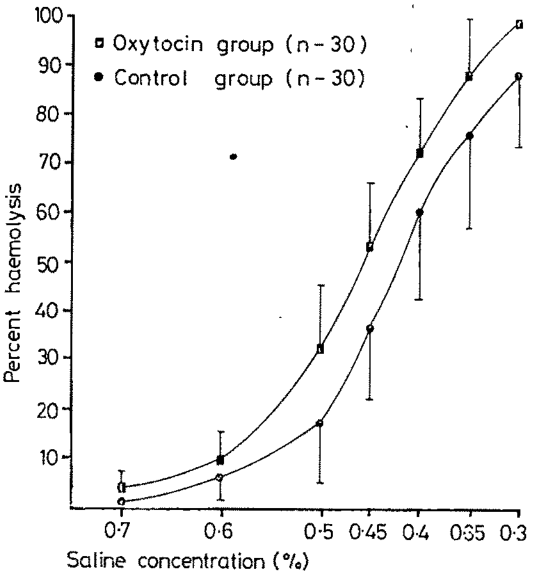

Fig. 1 *Significantly increased osmotic fragility of cord blood erythrocytes in neonates born after oxytocin infusion during labour is compared with control group. Bars show standard deviation.*

Results

Both groups were comparable as regards distribution of birthweights (2·83 ± SD 0·34 and 2·79 ± SD 0·41 kg respectively), gestational age (38·7 ± SD 1·8 and 39 ± SD 1·5 weeks respectively), asphyxia neonatorum, and maternal pre-eclamptic toxaemia. Cord serum sodium level was 131·3 ± SD 7·0 mmol/l and osmolality 273·4 ± 16·6 mmol/kg in group 1. These values were significantly higher in group 2—namely, cord serum sodium level 137·4 ± SD 5·3 mmol/l and osmolality 288·0 ± SD 8·4 mmol/kg (P<0·01 to <0·001). Haemolysis started at a higher saline concentration and was completed earlier in group 1 (Fig. 1). Serum bilirubin at birth was 30 ± 10 μmol/l (1·73 ± SD 0·6 mg/100 ml) in group 1, and 29 ± 9 μmol/l (1·69 ± SD 0·5 mg/100 ml) in group 2. At age 72 ± 12 hours, babies in group 1 attained significantly higher mean serum bilirubin levels of 166 ± 51 μmol/l (9·7 ± SD 3·0 mg/100 ml) compared with 113 ± SD 44 μmol/l (6·6 ± 2·6 mg/100 ml) in group 2.

A significantly negative correlation was found between cord serum sodium and osmolality, and serum bilirubin at 72 ± 12 hours of age (Fig. 2). Babies with cord serum sodium level up to 125

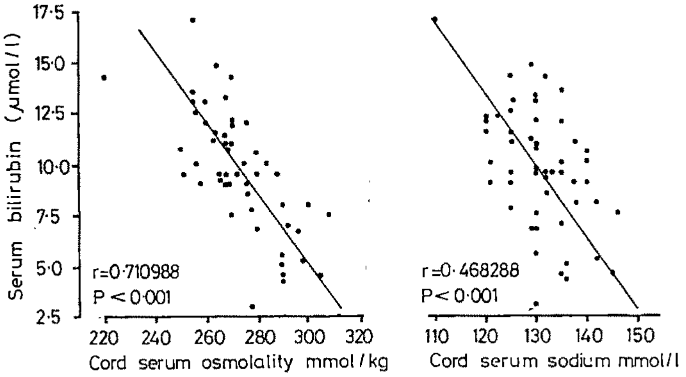

Fig. 2 *Negative correlation between cord serum osmolality and sodium, and serum bilirubin level at postnatal age 72 ± 12 hours.*

mmol/l had a mean serum bilirubin level of 195 ± SD 41 μmol/l (11·4 ± SD 2·4 mg/100 ml). Those with cord serum sodium levels between 126 and 135 mmol/l, and above 135 mmol/l had a mean serum bilirubin level of 163 ± SD 53 μmol/l (9·53 ± SD 3·08 mg/100 ml) and 131 ± SD 41 μmol/l (7·66 ± SD 2·41 mg/100 ml) respectively. The difference is statistically significant ($P<0·01$).

The hyponatraemia observed at birth in group 1 had disappeared by 72± 12 hours, when serum sodium levels were identical in the two groups (136·53 ± SD 6·07 mmol/l in group 1 and 138·12 ± SD 4·58 mmol/l in group 2).

Discussion

The findings in this study show that oxytocin infusion during labour results in transplacental hyponatraemia and hypo-osmolality, increased osmotic fragility of cord blood erythrocytes, and a higher bilirubin level at postnatal age 72 ± 12 hours. The negative correlation between cord serum sodium and osmolality, and serum bilirubin at age 72 ± 12 hours, strengthens our previous observation that transplacental hyponatraemia and hypo-osmolality play a significant role in the pathogenesis of oxytocin-induced hyperbilirubinaemia (Singhi and Singh, 1977). It is well known that when administrated by continuous IV infusion, oxytocin by virtue of its antidiuretic effect results in expansion of maternal extracellular fluid (ECF) with dilutional hyponatraemia and hypo-osmolality (Abdul-Karim and Assali, 1961; Morgan *et al.*, 1977; Schwartz and Jones, 1978). Large amounts of electrolyte-free solution—namely 5% dextrose used as a vehicle for oxytocin infusion—further aggravate these changes. Since maternal and fetal body fluids are in constant transplacental equilibrium, an expansion of fetal ECF, with resultant neonatal hyponatraemia and hypo-osmolality follows (Battaglia *et al.*, 1960; Schwartz and Jones, 1978). When blood is rendered hypo-osmolal, there is an inflow of water into erythrocytes (Blum and Forster, 1970). As a result erythrocytes swell and become osmotically more fragile. Significantly enhanced osmotic fragility of cord blood erythrocytes in the present study supports this hypothesis. These swollen and hyperfragile erythrocytes are easily trapped by the spleen, resulting in net higher bilirubin.

Our observations suggest that caution should be exercised while using oxytocin for induction or augmentation of labour, especially when additional risk factors for hyperbilirubinaemia coexist. If oxytocin administration is unavoidable, maternal serum sodium and osmolality should be maintained within the normal range by using dextrose saline as a vehicle for oxytocin instead of plain dextrose solution. Cord serum sodium and, if possible, osmolality should be estimated in all babies born after oxytocin-induced or augmented labour. Infants with cord serum sodium level < 125 mmol/l and/or osmolality of < 260 mmol/kg are at risk of developing hyperbilirubinaemia and should be considered for prophylactic administration of phenobarbitone as an inducer of the hepatic microsomal enzyme system.

We thank Professor O. P. Ghai, Department of Paediatrics, All-India Institute of Medical Sciences, New Delhi for his encouragement and advice.

Early use of sodium nitroprusside in respiratory distress syndrome

Sir,

The management of respiratory distress syndrome (RDS) with continuous positive airways pressure and intermittent positive pressure ventilation (IPPV) is well established. Sometimes these measures are insufficient to maintain adequate oxygenation. A report from Liverpool (Abbott *et al.*, 1978) described the comparatively late use of sodium nitroprusside in a baby with RDS. We describe the early use of sodium nitroprusside in a baby with severe RDS.

A baby boy, son of a 21-year-old Kenyan-Asian, was born at 28 weeks' gestation and weighed 1·1 kg. His mother had been admitted 8 days before delivery with spontaneous rupture of membranes. 24 hours before delivery she had become pyrexial and been treated with cephradine. Dexamethasone and ritodrine were given during labour, and delivery was assisted by Wrigley's forceps. The baby needed IPPV for 15 minutes after birth and rapidly developed severe RDS which required ventilation within 2 hours of delivery. Pa_{O_2} was initially maintained at 10 kPa (75 mmHg), but at 6 hours it had fallen and could not be maintained above 4 kPa (30 mmHg). At this stage the ventilator settings were: ratio inspired:expired (I:E) 4:1, pressures I:E 25/5 cm H_2O, F_{IO_2} 0·9, ventilator rate 40/min.

Sodium bicarbonate infusion (2 mmol/kg per 24 hours) was begun at 4 hours, and sodium nitroprusside (120 μg/

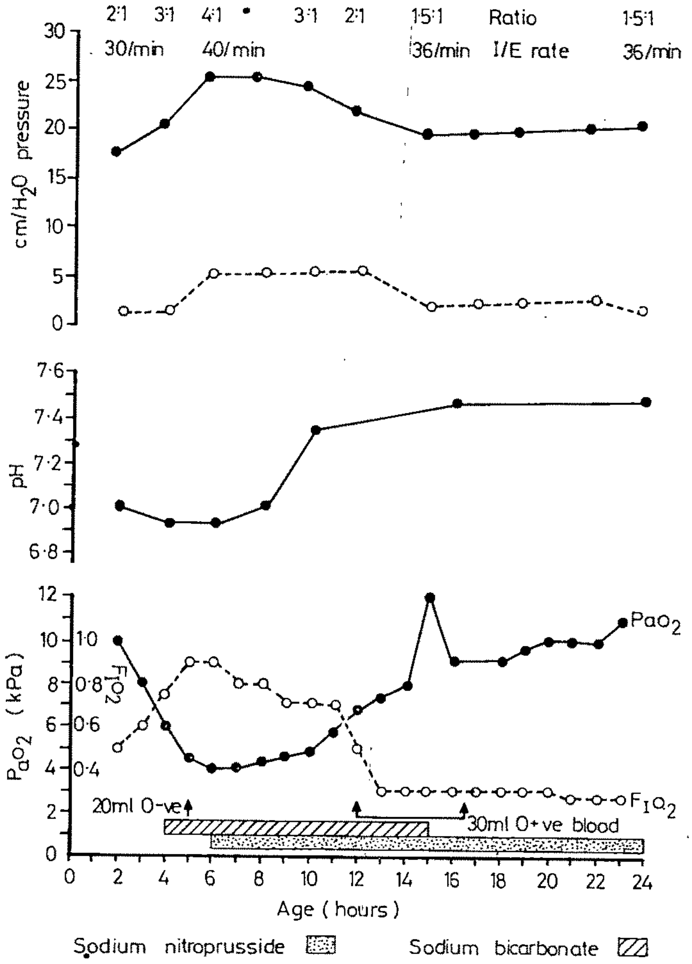

Figure *The early use of sodium nitroprusside in respiratory distress syndrome.*

kg per hour) at 6 hours. Fresh donor blood, total 50 ml, was transfused to maintain the systolic blood pressure above 50 mmHg. At 8 hours the baby's condition began to improve with an increase in Pao_2, and at 15 hours, Pao_2 could be maintained at 12 kPa (90 mmHg) with the following ventilator settings: ratio I:E 1·5:1, pressures I:E 18/2 cm H_2O, Fio_2 0·3, ventilator rate 36/min.

The sodium nitroprusside infusion was continued for 24 hours after which time the dose was logarithmically reduced every 12 hours until it was finally stopped at 72 hours. During the next 12 hours the blood pressure rose from 50/40 to 90/60 mmHg but it returned to normal 24 hours after discontinuing the infusion. The infant's progress in the first 24 hours of life is shown in the Figure.

The baby continued his difficult neonatal period with a respiratory tract infection on day 5 and a Gram-negative septicaemia on day 14. He was discharged home on day 56 and to date, at 3 months, shows normal development.

In RDS there is often very pronounced right-to-left shunting (Strang, 1966). Sodium nitroprusside is a direct-acting vasodilator (Tinker and Michenfelder, 1976) and its action on the pulmonary vascular bed reduces pulmonary vascular resistance, thereby increasing pulmonary blood flow. This decreases right-to-left shunting and results in an increased Pao_2.

Compared with the case in Liverpool, we gave sodium nitroprusside at a very early stage in the illness. The fact that this was followed by such a rapid improvement is convincing evidence of its therapeutic value. Thus sodium nitroprusside infusion may have an important role in the management of babies with severe RDS who deteriorate in spite of mechanical ventilation.

Attention has recently been drawn to the possible toxic effects of sodium nitroprusside (*British Medical Journal*, 1978). Our observation that 50 ml blood (about 57% of blood volume) was needed to maintain systolic blood pressure indicates that sodium nitroprusside should be used only if there are adequate facilities for biochemical and blood pressure monitoring.

Weaning very low birthweight infants from mechanical ventilation using intermittent mandatory ventilation and theophylline

Sir,

We read with interest the paper by Barr (*Archives*, 1978, **53**, 598), and should like to report our recent experience with aminophylline in two very low birthweight infants.

Case 1

This infant born at a gestational age of 30 weeks weighing 1190 g was severely asphyxiated at birth and required mechanical ventilation for the first 4 days of life. At age 4 weeks, 48 hours after the introduction of nasojejunal feeds, he developed necrotising enterocolitis and required a 40 cm small bowel resection. At the same time, mechanical ventilation was recommended because of recurrent apnoea and bradycardia: initial ventilator settings were: peak pressure 25 cm H_2O, positive end expiratory pressure 5 cm H_2O, and frequency 28 cycles/min.

During the next 6 days attempts to wean him from the ventilator by decreasing the rate to 16 cycles/min resulted in episodes of bradycardia and cyanosis with the capillary Pco_2 increasing from 4·7 to 7·9 kPa (35 to 59 mmHg). In view of this, aminophylline was administered with a loading dose of 3·3 mg/kg intravenously followed by a maintenance dose of 3 mg/kg per day in three divided doses. Serum aminophylline level 48 hours after starting treatment was 8 mg/l (therapeutic range 6·6–11 mg/l. 11 mg/l, Shannon *et al.*, 1975).

24 hours after the introduction of aminophylline, capillary Pco_2 had fallen to 5·3 kPa (40 mmHg); there had been no change in the ventilator settings. The infant was then successfully weaned from the ventilator.

Case 2

This infant was also born at 30 weeks' gestation and weighed 1150 g. At age 12 days he began to have episodes of apnoea and bradycardia. Capillary blood-gases at this stage showed a Pco_2 of 8·9 kPa (67 mmHg). Biochemical and infective causes for the apnoea were excluded while the chest *x*-ray was compatible with early chronic lung disease of prematurity. A loading dose of 3·8 mg/kg aminophylline was given intravenously followed by a maintenance dose of 3·1 mg/kg per day in three divided doses. Serum aminophylline level 48 hours after starting treatment was 6·5 mg/l. 24 hours after the loading dose of aminophylline, the capillary Pco_2 had fallen to 6·3 kPa (47 mmHg) with no recurrence of the apnoea.

Our results support Barr's observations that aminophylline may be an aid in the weaning of infants from mechanical ventilation and, like caffeine (Aranda *et al.*, 1977), will reduce the Pco_2, probably by increasing the ventilatory effort and thereby increasing alveolar ventilation.

Bilateral Wilms's tumour in Klippel-Trenaunay syndrome

Sir,

Involvement of the viscera, including the kidneys, is not uncommon in the Klippel-Trenaunay syndrome (KTS) (haemangiectatic hypertrophy) but the occurrence of Wilms's tumour in KTS has not been described, although one child with bilateral nephroblastomatosis and KTS is known (Mankad *et al.*, 1974). We have recently observed an infant with KTS and bilateral Wilms's tumour.

The child presented from birth with typical signs of KTS (unilateral hypertrophy of the left ear, tonsil, labium majus, and lower extremity—especially the third toe—cutaneous haemangiomas on the trunk, subcutaneous haemangioma on the left thigh, hyperpigmentation at the right neck and arm). Psychomotor development was normal. At age one year, a left abdominal mass was found on routine examination. IVP showed an enlarged left kidney with distortion of the calyces. At laparatomy a nodular tumour originating from the left kidney was found and a nephrectomy performed. The right kidney showed small nodules which were biopsied. There was no evidence of metastasis at operation or in subsequent *x*-rays. The resected kidney measured 16 × 10 × 11 cm. The renal parenchyma was reduced to 8 mm thickness surrounding the tumour mass. Histologically glomerular and tubular differentiation and solid blastomatous structures were evident, consistent with Wilms's tumour. The biopsy of the right kidney showed similar lesions. Chemotherapy and radiation therapy were given. 12 months after nephrectomy the patient remains well.

Wilms's tumour has been reported in association with congenital hemihypertrophy, in the Beckwith-Wiedemann syndrome, and in association with aniridia.

Although a common embryological basis for KTS and Wilms's tumour is not yet established, the association may be more than chance.

Neonatal effects of maternal clomipramine therapy

Sir,

We read with interest the study by Crome and Braithwaite (*Archives*, 1978, **53**, 902). We encountered a similar problem recently in a neonate affected by maternal clomipramine (Anafranil) in which the main problems were instability of body temperature and jitterness.

The mother has been taking clomipramine, 25 mg three times a day for 18 months for depression, and this treatment continued unchanged throughout her normal pregnancy. The baby boy born at term had a birthweight of 3·14 kg, and a normal Apgar score, but at 12 hours he became dusky during feeding and had a rectal temperature of 35·4°C. His tendency to hypothermia was aggravated by feeding and handling, and persisted for 4 days. No biochemical or infective cause was found for this or for subsequent problems.

He became jittery on the 2nd day of life and this continued for 48 hours; perhaps this was the effect of drug withdrawal. Treatment with phenobarbitone (10 mg/kg per day) controlled this problem and may have induced the hepatic conjugating enzymes needed to metabolise clomipramine.

Plasma clomipramine levels in the baby were <20 μg/l on the 1st and 3rd days of life, but the corresponding levels of its active metabolite, chlordesipramine, were higher at 116 and 96 μg/l.

The baby made an uneventful recovery and was making normal developmental progress at ages 3 and 6 months.

The use of tricyclic antidepressant drugs in pregnancy has been linked with the birth of malformed infants (Barson, 1972; Idänpään-Heikkilä and Saxén, 1973), but little is recorded about the associated neonatal morbidity. Hypothermia has been noted as a side effect of clomipramine treatment in adults, but this was not found by Crome and Braithwaite in their review of tricyclic drug poisoning in older children.

The frequency of the use of antidepressant drugs in pregnancy is unknown, but they should be avoided if possible.

We acknowledge the help of the National Poisons Information service at New Cross Hospital, Poisons Unit, London, which carried out the estimation of plasma drug concentrations.

Evaluation of the Sheffield system for identifying children at risk from unexpected death in infancy

Sir,

The conclusions drawn by Oakley *et al.* (*Archives*, 1978, **53**, 649) are so at variance with the data they present that we must comment. Briefly, the re-analysis below shows that the birth data from Birmingham and Newcastle are remarkably similar and are consistent with the two sets of Sheffield birth data (Protestos *et al.*, 1973; Carpenter *et al.*, 1977). Also the hypothesis that the birth scoring system (Carpenter *et al.*, 1977) would be equally effective in Birmingham, Newcastle, and Sheffield is not rejected ($P = 0\cdot14$). Furthermore, although our birth scoring system performed relatively poorly on the Birmingham data compared with Sheffield, its level of performance there is the same as that of the scoring system studied by Alberman and Goldstein (1970) when it was shown that maximum benefit is gained by the differential allocation of resources to a high-risk group.

Table 3 of Oakley *et al.* (1978) appears to show that the birth data from Birmingham differ from those collected in Newcastle, and the text indicates that this is how the authors view their data. Their mistake arises from the method of analysis. For example, invasive investigations in pregnancy are reported as significantly associated with the Birmingham cases but not with Newcastle ones. What is not apparent is that the difference between Birmingham cases and controls is smaller than the difference between cases and controls in Newcastle in this respect, as shown in Table C1.

Table C1 *Percentage differences between cases of unexpected death and live controls in Birmingham and Newcastle*

Variable	*City*	*Cases (%)*	*Controls (%)*	*Percentage difference*
Invasive investigations during pregnancy	Birmingham	32·5	26·5	6·0
	Newcastle	19·6	12·5	7·1
Sex	Birmingham	51·8	57·8	−6·0
	Newcastle	69·6	46·4	23·2

Re-analysis of risks associated with factors. The question then arises, Is there any evidence that their data from Birmingham and Newcastle differ in regard to the risks of unexpected death associated with the 18 factors they list? There are several approximate statistical methods for examining this question. We have used the exact method of Zelen (1971) and have applied it to the data presented in Table 3 of the paper by Oakley *et al.* The only significant difference ($P = 0\cdot025$) between the two sets of data is that relating to sex, Table C1. This is mainly because the proportion of male cases in Birmingham is unusually low (51·8%) while that in Newcastle is exceptionally high (69·6%) (Carpenter, 1972). At least one P value as small as this may occur by chance in 18 significance tests.

The overall impression is that the two data sets are remarkably similar. The average P value for the 18 tests of homogeneity is 0·72 which is substantially larger than the expected value of 0·5. If the 18 comparisons are regarded as independent, the two sets of data appear significantly similar ($P<0\cdot00003$), but the variables are all interrelated which probably accounts for the unexpected similarity. For 5 factors: birthweight, twin birth, urinary tract infection during pregnancy, gestation <37 weeks, and admission to special care baby unit, the relative risks cannot be more similar, given the number of infants with the factor in each set of data.

Having found that the data from Birmingham and Newcastle are essentially similar, are they compatible with the findings of the two surveys of birth data in Sheffield reported by Protestos *et al.* (1973) and Carpenter *et al.* (1977)? Our analysis is confined to 7 of the 8 factors in the birth scoring system described by Carpenter *et al.* (1977). We cannot include the 2nd stage of labour because the data are grouped differently. For each factor, we tested whether the 4 estimates of relative risk, derived from the 4 data sets, could be regarded as homogeneous. In no case was the hypothesis of homogeneity rejected. The smallest P value was 0·085 for mother's blood group. This is hardly surprising because the two Sheffield data sets are significantly different in respect of mother's blood group (Carpenter *et al.*, 1977). Combining the 7 significance tests also provided no suggestion of heterogeneity.

Consequently the best information available is provided by combining all the data. The results of doing so are presented in Table C2 which shows that the differences are significant for each of the 7 variables. Differences are similar to those previously reported by Carpenter *et al.* (1977).

Table C2 *Combined birth data from Birmingham, Newcastle, and two Sheffield surveys.* (*334 cases of unexpected infant death and 389 live controls*)

	Cases (%)	*Controls (%)*	*Percentage difference**	*P*
Mother's age <24	60·8	43·8	17·0	0·000008
Birthweight <3000 g	45·3	27·1	18·2	0·0000006
Intention to breast feed	20·5	31·4	−10·9	0·0014
Primiparous	22·7	37·0	−14·3	0·00005
Twins	5·7	0·5	5·2	0·00009
Urinary tract infection	12·4	7·3	5·1	0·0375
Blood group A	35·4	46·3	−10·9	0·0041

*Combining the four data sets by Cochran's test (Armitage, 1971) gives mean % differences which are up to 1·2% smaller and which are slightly less significant. But exact tests (Zelen, 1971) of the combined relative risks are more significant than shown.

Birth scoring. Using stepwise discriminant analysis, Oakley *et al.* (1978) obtained discriminant functions for Birmingham and Newcastle which had only 3 variables in common, only one of which was included in our birth scoring system—i.e. mother's age. The reader is left with the impression of a mass of heterogeneous data. Stepwise analyses are very arbitrary in their selection of variables and heterogeneity can be established only by formulating and testing the appropriate hypothesis. Oakley *et al.* give no hint that this has been done, nor have they tested whether their data conflict with our scoring system. All their analysis shows is that if we had started with one of their sets of data we might be using a scoring system which superficially would look very different from our present one.

Oakley *et al.* report the results of applying our second scoring system to their data. Testing the hypothesis that infants with scores >500 are at the same risk in Birmingham and Newcastle we find P = 0·13. When we compare their results with our evaluation (Table 9 of Carpenter *et al.*, 1977) we again find no significant differences (P = 0·14). Taking all these data together, 54% of cases had scores >500 compared with 30% of controls. It is now clear that the choice of 500 as the critical score is too low if the high risk group is only to include about 16% of controls. Raising the critical score also reduces the proportion of cases in the high risk group. In any case there is no good reason for merely considering high and low risk groups as risk rises exponentially with score.

The principal criticism of Oakley *et al.* is that 'the degree of discrimination that the Sheffield "at birth" score achieved in either Birmingham or Newcastle during the study period is not one that would be of use in a prospective prevention programme, . . ." Sensitivity and specificity may be combined in the Youden index, J (Armitage, 1971) which is simply the difference between the percentage of cases and controls in the high risk group. For our prospective study, J = 38%; for the Newcastle data, J = 34%; for the Birmingham data, J = 13%. Alberman and Goldstein (1970) made a statistical evaluation of at-risk registers and showed that maximum benefit is gained by the differential allocation of resources to a high risk group. The value of J for the risk register they discussed is 13%, which is identical with that observed in Birmingham.

We have never said that the scoring system developed for identifying high-risk infants in Sheffield would work in other cities. The wide range of postperinatal mortality rates indicates that differences between cities are likely, but so far the reported differences may be attributed to random variation. We believe a scoring system along the lines we have described provides a practical method of improving the effectiveness of primary care.

Drs Oakley and Stanton comment:

Our co-author Mrs J. Tavaré is now living in the USA, and we have had insufficient time to obtain her reply to the comments of Dr Carpenter and his colleagues on the statistical methods used in our paper.

There are always many ways of analysing a particular data set. Dr Carpenter and his colleagues are right in observing that our paper was primarily concerned with the *practical* application of the Sheffield scoring system to prospective prevention programmes, although we confirmed that the system discriminated at a statistically significant level between children who die, and the living control population.

A system which in Birmingham identified fewer than half the children who subsequently died while scoring one-third of the normal population at risk may be statistically valid, but we believe it has no place in primary care where we are dealing with the lives of infants and not statistics. Using the present system could well result in a positive maldistribution of primary care services by creating a false sense of security, and directing attention away from potentially vulnerable children who do not score at risk.

It is possible that future work in the Department of Health and Social Security's Multicentre Postneonatal Study will produce an effective at-risk system. Meanwhile, we are still of the opinion that scoring systems should only be used as research tools to indicate groups of infants that require particular study to investigate the aetiological factors of the sudden infant death syndrome.

Book reviews

Paediatric Therapeutics. Edited by H. B. Valman. (Pp. 231; illustrated + tables. £7·75 paperback.) Blackwell: Oxford. 1979.

Any book devoted solely to treatment inevitably raises a doubt—is it really feasible to separate treatment from diagnosis, prognosis, and the rest? This principle apart, the rate of change of treatments tends to be rapid, new techniques and new drugs are being introduced all the time, old drugs and antibiotics are re-evaluated, given in different dosages, or become ineffective for various reasons, such as bacterial resistance. Hence I have hitherto looked with little favour on those massive and wordy volumes devoted to paediatric therapy which are almost as big as a complete textbook of paediatrics. Within a year or two they are already out of date and are to be seen growing dusty and unused on the shelves.

Coming to this book, my prejudices were disarmed by finding that both O. H. Wolff in his Foreword and the Editor in his Preface themselves frankly discuss the objections to books devoted solely to treatment, and they supply arguments to justify publication of this particular book. Firstly, we seem to be entering a new era where drugs can be used more rationally, based on expanding knowledge of their pharmokinetics and the increasing use of measurements of serum levels. So the first 3 of the book's 12 chapters are sensibly devoted to the fundamental aspects of the subject.

Secondly, the unpretentious format of the book, a paperback of 230 pages with a limited number of authors, has enabled rapid publication (I noted at least one 1978 reference) and will, it is to be expected, facilitate frequent new editions.

The remaining 9 chapters are devoted to epilepsy (B. D. Bower, to whom thanks for his forthright appraisal of phenobarbitone 'probably has little place . . .',) urinary infections (J. M. Smellie), nephrosis (T. M. Barratt), respiratory infections (H. Simpson), asthma (R. S. Jones), gastroenteritis (H. B. Valman), neonatal bacterial infection (P. M. Davies), leukaemia (T. M. McElwain), and diabetes (D. B. Grant). Judged by the criterion of whether an article provides something more than merely dealing with its subject in a way any standard textbook might do, I judged the majority did so, but there did seem very little new to say about the therapy of either gastroenteritis or diabetes.

One minor and possibly pedantic quibble, although drug dosage expressed as mg/kg/day is admittedly understood by everybody, this strictly does not mean mg. kg^{-1}. day^{-1} and would be better eliminated from a book designed to make clinical medicine more scientific.

In sum, an admirable book which should be the forerunner of many editions.

DOUGLAS GAIRDNER

Pulmonary Disease of the Fetus, Newborn, and Child. Edited by E. M. Scarpelli, P. A. M. Auld, and H. S. Goldman. (Pp. 680; illustrated + tables. £37·50 hardback.) Lea & Febiger: Philadelphia. 1978.

This is the companion volume to *Pulmonary Physiology of the Fetus, Newborn, and Child* (1975). There are no fewer than 23 contributors to the 19 chapters and the problems of multiple authorship have not been entirely overcome, stricter editing might have avoided some of the pitfalls and resulted in a smaller, less expensiv book.

The best chapters are those dealing wit intensive care; in particular, the one o airway management and cardiopulmonar resuscitation is a model of clarity an brevity. There are also 2 chapters devote to neonatal intensive care and the variou forms of respiratory distress in the newborn. Each contains some excellen practical guidelines although some of th advice given—for example, on the use an abuse of umbilical catheters—would b highly controversial in this country; fo some inexplicable reason these 2 chapter are irritatingly separated by one on th pathology of developmental anomalies o the lung. A section on thoracic surger includes quite a lot of surgical techniqu which, although not sufficiently detaile for surgeons, contains helpful hints fo paediatricians who are left 'holding th baby' postoperatively. The chapter o pulmonary radiology contains many clea *x*-rays illustrating the common and som very uncommon conditions; there ar also practical tips on how to interpre unusual *x*-ray appearances. The section on infections and chronic pulmonar disease are competent but unexceptional The remaining chapters deal with genera topics—such as, pathophysiology, inhalation therapy anaesthesia, sudde infant death, and extrapulmonary disease Each chapter is supplemented with usefu references.

Taken as a whole this book gives reasonable overall view of respirator diseases and their management. It woul be of value to the general paediatricia who is called upon to deal with acut and chronic respiratory problems, but i cannot be recommended as an unqualifie 'best buy'.

GILLIAN GAND

NEW FROM CHURCHILL LIVINGSTONE

The Liver and Biliary System in Infants and Children
Edited by R. K. Chandra
352 pages 143 half-tone + 49 line illustrations hardback £20.00 approx

The Publishing Manager, JOURNAL OF CLINICAL PATHOLOGY, BMA House, Tavistock Square, London WC1H 9JR

Reduced Subscription Rates for Junior Hospital Doctors Residents and Interns...

from January 1 1979

Archives of Disease in Childhood

will be available to junior doctors in all parts of the world for a maximum of four consecutive years at REDUCED Annual Subscription Rates. (Thereafter, or when reaching consultant status this special offer will no longer apply.) The following subscription rates apply for the twelve issues published in 1979.

Inland £17.00

Overseas US$40.00

(The full rates are: Inland £28.00; Overseas US$65.50)

The opportunity to subscribe to this journal of international authority and repute at a substantially reduced subscription rate is one not to be missed by junior doctors seeking to specialise in paediatrics.

Please complete the adjacent order form and send for your subscription NOW.

Further order forms can be supplied on request.

Archives of Disease in Childhood

New books from

Blackwell

Clinical Paediatric Physiology

Edited by S. Godfrey M.D. Ph.D. F.R.C.P. and J.D. Baum M.A. M.Sc. M.D. F.R.C.P. 1979. 546 pages, 125 illustrations. About £22.50

All those interested in the physiological principles underlying the practice of good clinical paediatrics either as clinicians or as senior students will find this book invaluable. Each chapter is written by a specialist in the field and is an authoritative interpretation of applied clinical physiology, rather than a research oriented monograph.

Metabolic Disease in Childhood

L. Sinclair M.B. B.Sc. F.R.C.P. D.C.H. 1979. 584 pages, 115 illustrations. About £27.50

This work is designed to clarify the subject of metabolic disease in childhood so that clinicians may be able to appreciate the scientific basis of the subject and the laboratory worker may better understand the clinical problems. The text is intended to interest the reader and keep him up to date with not only recent biochemical advances but also changes in attitude to those afflicted by metabolic handicap.

A Reference Manual of Growth and Development

J.M.H. Buckler M.A. D.M. F.R.C.P. 1979. 112 pages, 40 illustrations. £5.50

This volume presents easily-accessible data on the growth and development of normal children in graphical percentile forms and tables. Normal values are illustrated together with their interpretation and application. It is designed as a convenient reference manual for all medical staff working with children.

Paediatric Therapeutics

Edited by H.B. Valman M.D. F.R.C.P. D.C.H. 1979. 240 pages, 21 illustrations. Paper, £7.75

The management of common paediatric therapeutic problems is outlined in this book. The first three chapters deal with the scientific principles on which rational treatment is based. Each of the remaining chapters is concerned with a specific clinical problem and is written by an authority in that field. It is aimed at the postgraduate student but family doctors and undergraduate students will find it an up-to-date guide to a rapidly changing subject.

Blackwell Scientific Publications

Diseases of the respiratory and urinary systems account for a high proportion of all consultations in general practice, justifying the 200 pages devoted to them in

TODAY'S TREATMENT/3

The remaining section deals with the use of antibiotics across the whole spectrum of medicine, looking at the advantages and drawbacks of the major categories and their use in clinical settings where decision-making may be difficult. Like its predecessors, *Today's Treatment/3* concentrates on practical issues and provides the busy clinician with the information he needs in his day to day practice.

Price: Inland £5.50
Abroad US$13.75

(Concessionary price to BMA members: Inland £5·00; Abroad US $12·50)

ARCHIVES OF DISEASE IN CHILDHOOD

The Journal of the British Paediatric Association

Original articles

Clinical events relating to intraventricular haemorrhage in the newborn *M. Fujimura, D. M. Salisbury, R. O. Robinson, P. Howat, P. M. Emerson, J. W. Keeling, and J. P. M. Tizard* 409

Effect of feeding on neonatal oxygen consumption *J. K. Stothers and R. M. Warner* 415

Hearing loss in very low birthweight infants treated with neonatal intensive care *S. J. Abramovich, S. Gregory, M. Slemick, and A. Stewart* 421

1028 neonatal electrocardiograms *R. W. A. Jones, C. Sharp, L. R. Rabb, B. R. Lambert, and D. A. Chamberlain* 427

Sinusoidal heart rate rhythms in severe neonatal hypoxia *M. McC. Reid, J. Jenkins, and G. McClure* 432

Breath hydrogen test for detecting lactose malabsorption in infants and children. Prevalence of lactose malabsorption in Japanese children and adults *O. Nose, Y. Iida, H. Kai, T. Harada, M. Ogawa, and H. Yabuuchi* 436

Giant exomphalos—conservative or operative treatment? *D. C. S. Gough and A. W. Auldist* 441

Defective Candida killing in childhood malnutrition *R. Tuck, V. Burke, M. Gracey, A. Malajczuk, and Sunoto* 445

Bronchial asthma in Nigerian children *W. I. Aderele* 448

Carbamazepine dose-frequency requirement in children *G. W. Rylance, T. A. Moreland, and G. M. Butcher* 454

Osteoid osteoma and benign osteoblastoma in childhood *J. A. Black, R. K. Levick, and W. J. W. Sharrard* 459

Cushing's disease presenting with growth failure: clinical remission during cyproheptadine therapy *D. B. Grant and S. M. Atherden* 466

Short reports

Rectal paracetamol in small children with fever *S. Vernon, C. Bacon, and D. Weightman* 469

Acute infantile thrombocytosis and vitamin K deficiency associated with intracranial haemorrhage *J. Lorber, J. S. Lilleyman, and E. B. Peile* 471

Premature menarche without other evidence of precocious puberty *M. E. Heller, J. Dewhurst, and D. B. Grant* 472

A boy with low-TSH hypothyroidism *P. J. Smail, T. E. Isles, and R. S. Ackroyd* 475

Ring 20 chromosome in a child with seizures, minor anomalies, and retardation *J. M. Stewart, N. Cavanagh, and D. T. Hughes* 477

Notice to Contributors

Papers for publication should be sent to the Editors, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR. Submission of a paper will be held to imply that it contains original work which has not been previously published. Permission to republish must be obtained from the Editors.

Short reports. Case reports, brief laboratory observations, preliminary communications, and other short papers may be submitted for this section. Length must not exceed two printed pages of the *Archives*, i.e. in general not more than 1000 words of text, two figures *or* tables, and eight references. Single case reports will usually only be considered in this form.

For guidance on ethical aspects authors should refer to Editorials in this Journal (1967, **42**, 109; 1973, **48**, 751; 1978, **53**, 441).

One page proof will be sent to the author submitting the paper.

Reprints. Twenty-five reprints are supplied free and further reprints may be ordered when the proof is returned.

Authors should check the following requirements before submitting a paper:

(1) Scripts to be top copy and typed in double spacing.
(2) SI units. The units in which the work was done will appear first with the other units, i.e. SI or traditional units, appearing after in parentheses. A conversion factor should be given as a footnote to tables, and in legends to figures.
(3) Institution(s) where work done to be stated.
(4) Address and position of author(s) to be given.
(5) Name and address of author supplying reprints to be given at end of paper.
(6) Figures: (*a*) provided with a caption, typed on a separate sheet, (*b*) referred to in the text.
(7) Diagrams to be drawn on stout white paper; any lettering may be lightly inserted in pencil.
(8) Photographs to be on glossy paper unmounted, and trimmed to include only relevant portion. Any lettering, etc. to be inserted should be indicated on a separate transparent sheet.
(9) Coloured illustrations may be considered, but the author will usually be asked to contribute to the cost.
(10) Tables (numbered, with titles) typed on to separate sheets. Large tables are expensive and are not encouraged.
(11) From January 1980 references in the text will be numbered. References given at the end of the paper should be listed in the order in which they are first mentioned. The full title of article or book should be given, and the first and last page numbers of the particular paper or chapter. The titles of journals should be abbreviated according to the style used in Index Medicus (see *British Medical Journal*, 24 February 1979, **1**, 532–535).
(12) Summary to be typed on a separate sheet; and it should say what was done and what was concluded.

Notice to Advertisers

Applications for advertising space and rates should be made to the Advertisement Manager, *Archives of Disease in Childhood*, B.M.A. House, Tavistock Square, London WC1H 9JR.

Notice to Subscribers

Archives of Disease in Childhood is published monthly. The subscription rate is £28.00 in the United Kingdom and the Republic of Ireland, and US $65.50 in all countries overseas. Payment for overseas subscriptions should be made in US dollars, i.e. US $65.50, or in your national currency based on the prevailing exchange rate to the US dollar of that currency, payable to the British Medical Association. Orders can also be placed locally through any leading subscription agent or bookseller. (For the convenience of readers in the USA subscription orders, with or without payment, can also be sent to: BRITISH MEDICAL JOURNAL, 1172 Commonwealth Avenue, Boston, Mass., 02134. All inquiries, however, must be addressed to the publisher in London.)

All inquiries regarding air mail rates and single copies already published should be addressed to the publisher in London.

Multiple copying of the contents of the publication without permission is always illegal.

Lederspan 1ST —to last

1ST Lederspan – strong, long actin

Lederspan reduces redness, heat, swelling and joint effusion.

> “From our own observations with more than 200,000 injections of (Lederspan) into joints, bursae and tendon sheaths in over 2,000 patients, together with those of other observers, we conclude that (Lederspan) is the most potent and longest lasting form of intrasynovial corticosteroid with an average duration in our hands of 28 days with 20 mg injections.”[1]

Long acting Lederspan has a low dosage.

Because of the high potency of Lederspan, lower doses per injection tha other injectable steroids are normally possible. The following chart gives a guide based on recommendations on Lederspan dosage following extensive evaluation.

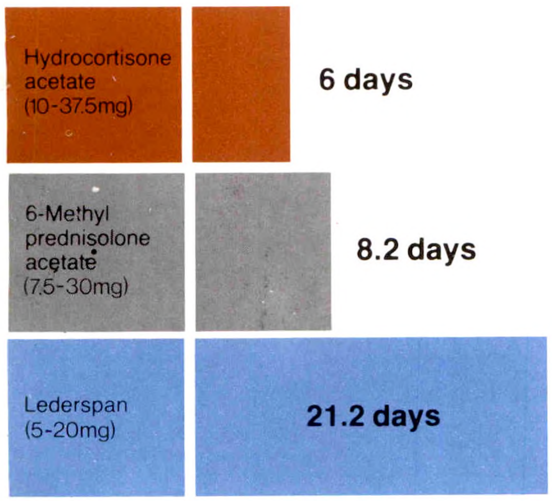
Dosage strengths comparing Hydrocortisone acetate, 6-Methyl prednisolone acetate, and Lederspan.[2]

	Hydrocortisone Acetate	6-Methyl Prednisolone Acetate	Lederspan
HIP	**37.5 mg**	**30 mg**	**20 mg**
KNEE	**37.5 mg**	**30 mg**	**20 mg**
SHOULDER	**25 mg**	**20 mg**	**15 mg**
ELBOW	**25 mg**	**20 mg**	**15 mg**
ANKLE	**25 mg**	**20 mg**	**15 mg**
WRIST	**18 mg**	**15 mg**	**10 mg**
HAND	**10 mg**	**7.5 mg**	**5 mg**
FOOT	**10 mg**	**7.5 mg**	**5 mg**

arenteral therapy for stiff and painful joints.

Lederspan has a longer duration of effect than other injectable steroids

Comparison between Hydrocortisone acetate, 6-Methyl prednisolone acetate, and Lederspan.[2]



Comparative duration of pain relief.

Lederspan injections are needed less frequently than other injectable steroids.

Lederspan. Minimal diffusion outside the injected area.

The very low incidence of systemic reactions[3] suggests that there is minimal diffusion outside the injected area.

In a trial comparing methylprednisolone with Lederspan (dosage 20 mg) ..."No serious side effects were observed."[3]

Local reactions are rare.

> *"None of our cases showed atrophy of the skin or subcutaneous tissue at the site of injection ..."*[4]

Long acting **Lederspan**
in 1 ml, and 5 ml vials.

LEDERSPAN* Suspension
Triamcinolone Hexacetonide 20 mg/ml
FOR INTRA-ARTICULAR AND INTRA-SYNOVIAL INJECTION
PRESCRIBING INFORMATION

DIRECTIONS FOR USE Strict asepsis is mandatory during administration. A topical anaesthetic spray or swab may be used locally before injection. The vial should first be shaken to achieve a uniform suspension. Since micronised triamcinolone hexacetonide has been designed for ease of administration, a small-bore needle (including 26 gauge needles) may be used.

If required Lederspan may be diluted immediately prior to injection with Water for Injection BP, Sodium Chloride Injection BP, Sodium Chloride and Dextrose Injection BP or, Lignocaine Hydrochloride Injection BP. Diluents should not contain parabens or phenol. A 5 mg/ml injection is also available.

By intra-articular and intra-synovial injection Lederspan should be injected directly into the affected joint, or synovial space. Excessive synovial fluid may be removed be aspiration before administering Lederspan. In treating conditions such as tendinitis or tenosynovitis care should be taken that Lederspan is injected into the space between the tendon sheath and tendon and not into the tendon itself.

DOSAGE Adults and Children By intra-articular and intra-synovial injection: 2-30 mg (0.1-1.5 ml) depending on the size of the joint, the degree of inflammation and the amount of fluid present. In general, large joints (such as knee, hip, shoulder) require 10-30 mg, whereas small joints (such as interphalangeal, metacarpophalangeal) require 2-6 mg. Since Lederspan provides prolonged activity, injections into a single joint or synovial space more frequently than every 3-4 weeks are not recommended. Repeated intra-articular injections should be as infrequent as possible,consistent with adequate patient care.

INDICATIONS FOR USE Triamcinolone Hexacetonide is a relatively insoluble corticosteroid (0.003% at 25° in water). It has a prolonged effect on tissue at the local injection side, the duration usually ranging from a few weeks to several months.

Lederspan is indicated in the treatment of rheumatoid arthritis, osteo-arthritis, traumatic arthritis, gouty arthitis, synovitis and bursitis, fibrositis, tendinitis, and epicondylitis, intermittent hydrarthrosis, and other subacute or chronic diseases where glucocorticoids can be expected to be useful.

CONTRA-INDICATIONS, WARNINGS ETC Contra-indications: Although active, latent or questionably healed tuberculosis, ocular herpes simplex and acute psychosis are generally considered to be absolute contra-indications to glucocorticoid therapy, the minimal systemic activity of triamcinolone hexacetonide after local injection might permit cautious use when indicated. The drug should not be used when there is history of hypersensitivity to any of the components of the formulation or when previous injections have produced local atrophy. Infected joints should not be injected with corticosteriods.

Precautions: As with other glucocorticoid agents, relative contra-indications are active peptic ulcer glomerulonephritis, myasthenia gravis, osteoporosis, fresh intestinal anastomoses, diverticulitis, thrombophlebitis, psychic disturbances, pregnancy, diabetes mellitus, hyperthyroidism, acute coronary artery disease, hypertension, limited cardiac reserve and local or systemic infections, including fungal and exanthematous diseases. The minimal systemic activity of this preparation, however, reduces the risks invloved in its use in the presence of the conditions. Not more than 2 or 3 joints should be treated simultaneously in the same patient.

Warnings and Side Effects: As with all glucocorticoids an exacerbation of symptoms or 'flare-up' may occur following intra-articular or intrasynovial injections. Local atrophy, burning, flushing, pain and swelling may occur. In addition, prolonged and repeated use in weight-bearing joints may result in further joint degeneration. This is probably related to premature use of still-diseased joints following relief of pain and other symptoms.

Systemic effects are rare with Lederspan due to its slow release from the injection site. In addition to those common to all glucocorticoids, some effects particularly associated with triamcinolone therapy are anorexia, myopathy and depression of mood.

If severe reactions or an acute infection develop during therapy, use of the drug should be discontinued and appropriate measures taken.

PHARMACEUTICAL PRECAUTIONS Lederspan should be stored at a temperature not exceeding 15°C.

Diluents containing methyl or propyl hydroxybenzoates (parabens) or phenol should be avoided since these tend to cause flocculation of the steroid.

LEGAL CATEGORY POM

MODERN TOPICS IN PAEDIATRIC DERMATOLOGY

Julian Verbov

In this, the first British book solely devoted to paediatric dermatology, eminent physicians and paediatricians have combined to produce a concise, clear account of the more important skin conditions seen in paediatric practice. It is designed with the broadest scope for the widest audience. Numerous illustrations, detailed tables and copious references illuminate the text throughout.

SEPARATION AND SPECIAL CARE BABY UNITS, CDM No. 68

F.S.W. Brimblecombe, M.P.M. Richards & N.R.C. Robertson

This book thoroughly investigates the present admission policies to special care units; the effects of separating newborn babies from their families, the visiting patterns of parents and the handling of babies by the nursing staff. It emphasizes the need for humanitarianism in introducing technological change.

HAEMORRHAGE, ISCHAEMIA AND THE PERINATAL BRAIN, CDM No. 68/70

Karen E. Pape & J.S. Wigglesworth

This volume focuses on an area of major importance in perinatal medicine. The authors, who have both made significant contributions to the subject of cerebral haemorrhage in the newborn, put forward many new and previously unpublished ideas. A feature of the book is the chapter on the vascular anatomy of the developing brain, which contains extensive new and original work, illustrated in colour. Intended primarily for the paediatrician, it should also be of particular interest to pathologists, obstetricians and others concerned with perinatal care.

Clinical events relating to intraventricular haemorrhage in the newborn

M. FUJIMURA, D. M. SALISBURY, R. O. ROBINSON, P. HOWAT, P. M. EMERSON,
J. W. KEELING, AND J. P. M. TIZARD

Department of Paediatrics, John Radcliffe Hospital, and Department of Pathology,
Radcliffe Infirmary, Oxford

SUMMARY Continuous measurements of arterial pressures, heart rates, respiratory movements, and respiratory rates were made from birth in 44 infants at risk from intraventricular haemorrhage (IVH). 17 babies died with IVH, in 10 of whom the event was timed objectively. Events in these babies were compared with survivors of similar birthweights, gestational ages, severity of birth asphyxia, and severity of hyaline membrane disease (HMD). IVH followed severe HMD and was associated with cessation of the babies' own respiratory efforts while on a ventilator and also with characteristic cardiorespiratory events. The minimum arterial pressure before IVH was lower than in comparable babies who survived. It is suggested that fluctuations of systemic blood pressure from initial low levels may be important in the pathogenesis of IVH. It is possible that changes in cerebral blood flow are of even greater significance.

Intraventricular haemorrhage (IVH) is a major cause of death in low birthweight infants. The succession of new ideas about its aetiology testifies to our continuing ignorance. These ideas have included cerebral congestion at birth (Schwartz, 1927), structural vulnerability of the immature germinal matrix (Ruchensteiner and Zollner, 1929; Hemsath, 1934), maternal toxaemia (Craig, 1938), hypoxic venous congestion and capillary damage (Gruenwald, 1951), venous stasis and infarction (Larroche, 1964; Ross and Dimette, 1965; Towbin, 1968; Leech and Kohman, 1974), coagulation disorders (Gray *et al.*, 1968; Schenck *et al.*, 1968; Cade *et al.*, 1969; Thomas and Burnard, 1973), acute severe hypoxia followed by a latent interval (Harrison *et al.*, 1968), jugular compression (Vert *et al.*, 1973), venous hypertension secondary to hypoxic cardiac failure (Cole *et al.*, 1974), hypertonic alkali solutions (Simmons *et al.*, 1974; Wigglesworth *et al.*, 1975), and changes in cerebral blood flow (Wigglesworth and Pape, 1978). While theories about events before or at birth are difficult to test, theories concerning events in postnatal life can be investigated. However it is essential to distinguish events preceding IVH —and possibly contributory to it—from those occurring during and after and possibly caused by IVH. We made continuous observations for up to 3 days after birth on infants of <33 weeks' gestation or <1500 g birthweight. In this paper the clinical events of those infants who died with IVH are described and related with events to the presumed time of the haemorrhage.

Patients and methods

44 infants <1500 g birthweights or <33 weeks' gestation were studied during a 15-month period from November 1974 (Fig. 1). 17 of these babies survived and serve as controls as none of them gave evidence of acute IVH in the neonatal period or has subsequently developed sequelae—such as hydrocephalus. Necropsy was performed on all 27 babies who died; 17 died with IVH. The babies dying without IVH were not used as controls as 3 died between 6 and 8 months after birth as a result of complications experienced in the perinatal period (and are not therefore comparable with neonatal

Table 1 *Details of babies dying with IVH and survivors*

	Babies dying with IVH (n=17)	*Survivors (n=17)*
Gestational age (weeks)	27·9 (26–32)	30·4 (27–33)
Birthweight (g)	1035 (650–1420)	1340 (630–2000)
Male : female	10 : 7	7 : 10

Figures in parentheses indicate the range.

deaths or survivors), and in only 3 of the remaining babies were arterial pressure measurements available. Details of the babies surviving and the babies dying with IVH are given in Table 1. 36 of the 44 (total study) babies had hyaline membrane disease (HMD) and 31 of these were ventilated. 16 of the 17 babies dying with IVH were ventilated because of severe HMD; IVH occurred in a baby with tracheo-oesophageal fistula after gastrostomy was performed. During the 15-month period of the study a further 47 babies of <1500 g birthweights or <33 weeks' gestation were admitted to our unit. These were not studied either because monitoring facilities were in use elsewhere, or because attempts to pass umbilical arterial catheters were unsuccessful, or because an umbilical arterial catheter passed at birth was removed only a few hours later as the clinical condition of the infant was good. Only 9 of these 47 babies died, 3 with IVH. The study group therefore did not represent the consecutive admissions in this birthweight gestational age group, and included a greater proportion of the most severely ill babies. Umbilical arterial catheters were introduced into 40 infants, generally at birth and certainly within 6 hours after birth. The catheter was passed to the level of L4 and the position confirmed by *x*-ray. Continuous arterial pressure measurements were made in 40 infants (Elcomatic pressure transducers) and recorded using a Devices M19 recorder. Mean hourly arterial pressures were derived manually by abstracting systolic and diastolic pressures from the records at 5-min intervals. The heart rate was derived either from the arterial pressure or from the ECG trace. Respiratory movements were recorded by a magnetometer (Rolfe, 1975) or by an impedance pneumograph (Air Shields Ltd), and from these, the respiratory rate was derived. A thermistor was inserted to 6 cm rectally and continuous core temperature was recorded (Electrolaboratoriet temperature recorder). In 12 infants an intravascular oxygen electrode (G. D. Searle Ltd) gave a continuous record of Pa_{O_2}. In all the infants blood-gas and pH measurements were made 4-hourly or at shorter intervals by the resident staff. Haematocrit was also measured 4-hourly on samples taken into dry syringes and measured in triplicate. Haemolysed samples were discarded. The infants were continuously observed by one of us in turn until death or recovery. Whenever a change occurred in the continuous records, any change in the infant's behaviour or environment was noted and vice versa. The occipito-frontal circumference was measured at least daily and up to 6-hourly in some infants with disposable paper tape measures.

IVH was timed by two methods described in detail elsewhere (Emerson *et al.*, 1977). Both methods depend on the effects of serial small blood transfusions given to improve tissue perfusion and oxygenation and to replace blood withdrawn for sampling. Comparison of the changes in proportions of transfused cells found in the intraventricular clot at necropsy restricted the timing of IVH to the period between two consecutive blood transfusions—'the IVH period'. By noting the rise in the proportion of transfused cells produced by infusion of a known red cell mass, changes in the baby's original red cell mass could be followed during life. A fall in fetal red cell mass occurred either before or during the period indicated by clot analysis. In this paper, 'before IVH' or 'during and after IVH' relate to the earliest time IVH could have occurred from the timing technique.

Results

Before IVH. Roberton and Tizard (1975) showed that establishment of adequate ventilation after resuscitation at birth is a powerful predictor for subsequent survival from HMD. Thus in analysing our results babies dying with IVH were divided into two groups (Fig. 1). Group 1 (n=9) were not able to support adequate ventilation from 15 minutes after birth. Group 2 (n=8) established spontaneous ventilation after resuscitation. Six of the 17 survivors were of comparable birthweights and gest-

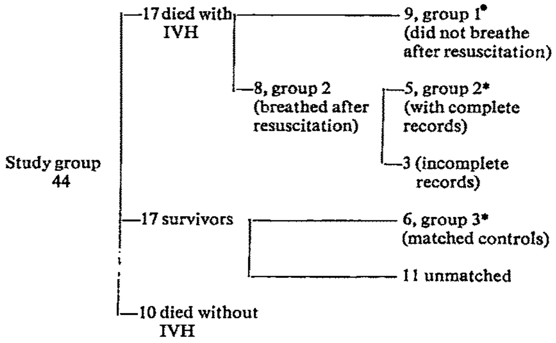

Fig. 1 *Division of the study group in order to identify comparable subgroups of babies (marked with an asterisk) who are likely to differ only with respect to factors specific for IVH (see text).*

Table 2 *Details of babies dying with IVH who breathed after initial resuscitation (group 2), and survivors matched for gestational ages (group 3)*

	Babies dying with IVH (n=5)	*Survivors (n=6)*
Gestational age (weeks)	29·1 (28–32)	29·2 (27–32)
Birthweight (g)	1153 (945–1420)	1152 (630–1860)
Male : female	4 : 1	2 : 4

Figures in parentheses indicate the range.

ations as group 2 and were ventilated for severe HMD; they are identified as group 3 (Table 2). The 9 babies in group 1 had gestational ages of 28 weeks or less and all but 2 were born by the breech. Their mothers went into labour spontaneously and preterm labour had not been anticipated. The 8 babies in group 2 and the 6 in group 3 had gestational ages of at least 28 weeks. All but one of group 2 were delivered by caesarean section for maternal indications; in group 3 there were 2 caesarean sections, one breech delivery, and 3 vertex deliveries.

In respect of the degree of birth asphyxia in each group, cord blood-gas and pH data (obtained immediately after birth from clamped sections of cord) were not sufficient to allow comparisons. Clinically, it is evident that the babies in group 1, none of whom maintained spontaneous respiration, were more severely asphyxiated at birth than those in groups 2 and 3 who initially maintained respiration after resuscitation. A comparison of groups 2 and 3 shows that at birth there were more severely asphyxiated babies in the latter—that is the survivors—but numbers are too small for statistical analysis. The core temperatures up to 6 hours after birth are shown in Table 3 for babies in groups 1, 2, and 3. The babies in group 1 had core temperatures lower at 2, 3, 5, and 6 hours after birth (P<0·05) than the remaining babies dying with IVH or survivors. Babies in groups 2 and 3 maintained similar core temperatures.

For all these reasons we considered that the babies in group 1 were different from those in groups 2 and 3 but that these last two groups are suitable for comparison. By choosing survivors of similar birthweights and gestational ages, all of whom were ventilated for severe HMD, we obtained two groups who were likely to differ only in respect to factors specific for IVH. In fact they were not comparable in respect of birth asphyxia (assessed clinically) in that the survivors (group 3) were in a poorer condition at birth than those in group 2. However all these babies (group 3) established spontaneous respiration within 15 minutes of delivery, and this appears to give a better prediction of survival than does the degree of asphyxia judged clinically. After excluding babies in whom attempts at umbilical arterial catheterisation or at timing of IVH were unsuccessful, 5 babies from group 2 were available for comparison with 6 survivors from group 3 (Table 2). Fig. 2 shows the mean hourly arterial pressures in groups 2 and 3, abstracted from the continuous records. The increase in mean arterial pressure by 6 hours after birth (estimated as a percentage change from the mean arterial pressure 2 hours after birth) was significantly greater in babies in group 2 than in group 3. Although the mean arterial pressures of the two groups were not significantly different from each other at any time after birth, this difference in relative change during the first 6 hours after birth appeared to be due to a rise in the mean arterial pressure from the low levels in babies in group 2, whereas in survivors the arterial pressure either remained stable or fell slightly. In 3 babies in group 2 there was an additional acute episode of hypotension after the first 6 hours after birth and preceding IVH. The mean of the lowest systolic arterial pressure in all 5 babies before IVH (26·8 ± 7·05 SD mmHg) was lower than the mean of the lowest systolic arterial pressure observed at any time in the 6 survivors (37·8 ± 5·9 SD mmHg). The mean of the highest blood pressure in group 2

was 59/34 ± 13/10 SD mmHg while it was 58/38 ± 5/6 SD mmHg in group 3.

Although all the babies in groups 2 and 3 were being mechanically ventilated and therefore attempts were being made to keep the blood-gases within acceptable limits, extremes of hypoxia and hypercapnia did occur. These extremes are shown in Table 4. The differences are not significant.

During and after IVH. In the likely consequences of IVH, babies in groups 1 and 2 did not differ from each other. The proportion of babies who had a significant fall in haematocrit, fits, or rise in anterior fontanelle tension was similar in each group. They are therefore considered together for comparison with babies surviving. Eight of the 17 babies dying with IVH had fits. In most these were tonic but occasionally a baby had a multi-focal clonic fit. Tonic fits were accompanied by pronounced cardiorespiratory events. An abrupt increase in arterial pressure accompanied by a falling heart rate was associated with a few deep inspiratory gasps, as shown in Fig. 3. In 3 babies similar cardiorespiratory events were not accompanied by visible fits. They were clearly distinguishable from fluctuations which occurred during severe acidosis in a few babies and which we interpreted as Traube-Hering waves. These cardiorespiratory events were not seen in any of the surviving babies. Examination of the respiratory wave form distinguished the babies' own respiratory efforts from movements induced by the ventilator. In 7 babies, respiratory efforts ceased during and after the IVH period. In 5 of the 17 babies (groups 1 and 2) there were dramatic cardiorespiratory events or failure of spontaneous respiratory efforts before there was any other sign of IVH. In 6 babies of the 12 in whom serial measurements of the occipito-frontal circumference were available, there was a mean increase in occipito-frontal circumference of 0·88 cm (range 0·3–1·5) after the IVH period. A mean fall in haematocrit of 0·125 (range 0·04–0·23) took place in the 12 babies in whom serial haematocrit measurements were available. A rise in anterior

THAM (ml) Mean	2·0	17·8	0·4

fontanelle tension as detected by palpation was noted in 8 babies. A sudden fall in pH to a value of <7·1 occurred in 8 babies Table 5 shows the alkali infused into babies of groups 2 and 3. It can be seen that the amounts of bicarbonate solution and tromethamine (THAM) were no different before the IVH period in group 2 from the totals given to group 3 but were much greater (THAM) during or after the IVH period The mean hourly infusion of base (1 mmol of sodium bicarbonate equivalent to 1 ml 6% THAM) before the IVH period in group 2 was 0·09 ml/kg per hour. In group 3 this was 0·08 ml/kg per hour for the first 72 hours

Discussion

The ability of an infant to breathe adequately within 15 minutes of birth was used to separate infants who subsequently had IVH into two groups; these groups differed from each other in other ways. The infants who were not able to support adequate ventilation within 15 minutes of birth (group 1) were of gestational ages 28 weeks or less and were acidotic at birth, usually considerably so. With the exception of one baby, all were born by the breech; this may reflect their prematurity and it has implications for the fate of premature infants who are to be born by the breech.

Babies in group 1 had significantly lower core temperatures in the first 6 hours after birth. Hypoxia and acidosis inhibit thermogenesis by brown fat (Oliver and Karlberg, 1963; Scopes and Ahmed, 1966). While we cannot be sure that the asphyxiated babies were not subjected to more cold stress during resuscitation after birth than the rest—particularly during umbilical catheterisation at birth—it is possible that the lower core temperature is due in part to inhibition of nonshivering thermogenesis. In the babies of group 1, the onset of IVH ranged from <2 to 21 hours after birth, estimated by the proportion of transfused cells in the IVH. IVH occurred despite rapid correction of hypothermia, hypotension, and acidosis. We suggest that the causes of IVH in this group operate before and during birth.

By contrast babies in group 2 who were of gestational ages of at least 28 weeks were nearly all delivered by elective caesarean section for maternal indications. They were not as asphyxiated at birth and all but one developed severe HMD. The onsets of the IVH periods in this group ranged from 12 to 72 hours after birth and were later than the onsets in group 1. In babies of group 2 it is reasonable to look for the causes of IVH after birth. Comparison with babies in group 3 which should identify factors specific for IVH has allowed us to test current hypotheses concerning the aetiology of this condition. It has been suggested, for example, that IVH may be precipitated by alkali administration (Simmons *et al.*, 1974; Wigglesworth, *et al.* 1975). The technique of timing the earliest occurrence of IVH allows comparisons to be made of the alkali administration before IVH rather than the administration needed as a consequence of IVH. The babies of group 2 who subsequently developed IVH were given no more alkali before the IVH period than surviving babies; some of them received no alkali before the IVH period.

Although babies in group 1 had core temperatures significantly lower than babies in group 2, babies in group 2 had similar core temperatures as survivors. Hypothermia therefore is unlikely to predispose to IVH. Similarly the greatest arterial pressure observed in babies subsequently dying with IVH was identical with that of babies surviving, and the extremes of blood-gases were no different in the two groups either, suggesting that hypoxia, hypercarbia, and acidosis were not specific factors in the aetiology of IVH. It would appear that IVH can occur in the presence of normal arterial pressure.

The pronounced cardiorespiratory events which took place at the time of IVH were associated with tonic movements and were thought to be a consequence of seizure activity. The importance of timing of IVH is seen in evaluating these events. As in 2 babies the cardiorespiratory events occurred before and in 3 babies they occurred during the IVH period, it is tempting to ascribe to them an aetiological role. However, in 3 babies they took place after the fall in fetal red cell mass and it is probable therefore that they occurred as a consequence rather than as a cause of IVH. The only distinguishing feature that emerged from our comparison of events before the IVH period in babies in group 2 with events in babies in group 3 was that of hypotension. Although there is no evidence to support the suggestion that this is a causative relationship, we suggest that any hypothesis for the cause of IVH should take this finding into account. It is suggested that resulting from severe birth asphyxia, IVH babies may be subjected to cerebral ischaemic hypoxia, and then on restoration of normal arterial pressure there are areas of 'luxury perfusion' in the subependymal layer sufficient to initiate subependymal haemorrhage. This then ruptures into the lateral ventricles. It is possible that cerebral blood flow is of more critical importance than systemic blood pressure, but the relationship between these two variables in the newborn has yet to be determined (Cooke *et al.*, 1977).

Turning to the events that took place during and after IVH, failure on the part of the baby to continue making spontaneous respiratory movements, while on the ventilator, was an equally reliable sign of IVH and accords with general clinical experience. A fall in haematocrit was a consistent finding during and after IVH and occurred either alone or in combination either with a rise in anterior fontanelle tension or with fits in 15 of the 17 babies dying with IVH. In addition, a fall in fetal red cell mass took place at the same time as the onset of other signs of IVH and was not observed in any surviving baby. Where a blood transfusion is given after the onset of IVH the diagnosis can be made during life, and is nearly always supported by close observations of clinical events.

The patients were under the care of Drs J. D. Baum, B. N. Bower, H. Ellis, M. Moncrieff, and D. Pickering, We should like to thank Dr P. Rolfe and Mr P. Sutton for their bioengineering assistance and Miss P. Townshend and her nursing colleagues for their help. P.H. was in receipt of a grant from the Medical Research Council (GE974–185c), and D.M.S. from the Sir William Coxen Trust Fund; M.F. was a British Council scholar.

Effect of feeding on neonatal oxygen consumption

J. K. STOTHERS AND RUTH M. WARNER

Department of Physiology, The London Hospital Medical College

SUMMARY Oxygen consumption was measured in 9 short-gestation infants before feeding and for an hour after, using a closed-circuit metabolism chamber. Using the same system, O_2 consumption of 9 term infants was measured for varying periods, beginning one hour from the end of the last feed. In the short-gestation infants a rise was found in the 15–45 minutes after feeding; O_2 consumption then fell, and after 60 minutes had reached prefeed levels. The term infants showed no decrease with time after the first hour, as would be expected if the effect of feeding on O_2 consumption extended beyond this. It is concluded that increased O_2 demand after appropriate feeding does not extend beyond one hour postprandially.

The first quantitative description of the effect of feeding on oxygen consumption ($\dot{V}O_2$) was reported by Lavoisier (1789). He found that, in a temperature of 32°C, $\dot{V}O_2$ of an adult rose about 50% above the resting value during digestion. Bidder and Schmidt (1877) attributed this rise to the 'work of digestion'. This concept of increased intestinal work was challenged by Benidict and Emmes (1912), who showed that $\dot{V}O_2$ rose equally in response to either intravenous or oral amino-acids. A succinct summary of the various theories of the cause of this rise was written by Kleiber (1961). Rubner (1902) introduced the term 'spezifischdynamische Wirkung', which possibly by mistranslation has become specific dynamic action (SDA).

Early measurements of SDA in infants were made by Rubner and Heubner in 1899. Unfortunately, they compared the metabolic rate of a healthy 7½-month-old girl with that of a malnourished boy of 3½ months, being then unaware of the effect of age and state of nutrition on basal metabolism. Techniques of measurement have now improved and Murlin *et al.* (1925) reported that the SDA of ordinary 'feedings' within the first 8 days of life was small, the largest increase being 12% after a feed of 12% lactose. Since then a variety of workers using different foods and in differing environments have reported increases from 6% (Levine *et al.*, 1927) to 32% (Gamalero and Crosato, 1958). Městyán *et al.* (1969) investigated the magnitude and thermoregulatory significance of the response to feeding in premature babies under carefully controlled conditions, and found an increase in metabolism of 30% after feeding a milk formula in a thermoneutral environment. Gentz *et al.* (1970), studying the influence of feeding in newborn pigs, reported that in previously unfed piglets there was a significant rise in $\dot{V}O_2$ after feeding: the maximum increase was about 45%. They did not, however, find the rise in those previously fed to be significant, although from their figures it was of the order of 10%. Gentz *et al.* (1976) also investigated short-gestation infants and those of diabetic and prediabetic mothers and reported a 10 to 30% rise in $\dot{V}O_2$ after feeding.

The length of time during which the rise persisted in the series of Městyán *et al.* (1969) was about 240 minutes, although prefeed values were approached about 150 minutes postprandially. In the piglets (Gentz *et al.*, 1970) the return to mean control values was about 500 minutes in the previously fasted group; no values were given for the previously fed piglets. The $\dot{V}O_2$ of infants (Gentz *et al.*, 1976) reached a maximum at 1 to 1½ hours and then slowly returned to prefeed values. In none of these series was sleep state taken into account. In the human infant this can have a significant effect on $\dot{V}O_2$ (Stothers and Warner, 1978).

If these figures of duration of response are a consistent feature of neonatal feeding, it would seem that the infant spends little time with a basal $\dot{V}O_2$, and that feeding imposes an almost constant increase in oxygen demand. The aims of the present study were to observe the effect of feeding on $\dot{V}O_2$ with special reference to the length of time such an effect persisted, and to observe if the variation of

$\dot{V}O_2$ with sleep state in the short-gestation infant was similar to that of the term infant in a thermoneutral environment.

Material and methods

$\dot{V}O_2$ was measured in the closed-circuit metabolism chamber described by Hill and Rahimtulla (1965), modified by Hey and Katz (1969). The infants were from the maternity wards and the special baby care unit of this hospital. Each baby was studied with the informed consent of the mother and usually in her presence. Because it was considered unethical to administer nasogastric feeds to normal, term infants, two separate studies were undertaken.

In the first series 9 short-gestation but otherwise well infants were measured (Table 1). At the time of measurement all were being nasogastrically fed. In the second, observations were made of 9 term babies, 8 of whom were being breast fed and one bottle fed, all on demand. In both studies the infants were measured prone, in a thermoneutral environment, the appropriate temperature having been calculated from the data of Hey (1969). In each case the rectal temperature was measured throughout the period of observation. Minute-by-minute records of behavioural states were made by an experienced observer, continuously watching the infant for body and eye movements. Periods which contained more than one significant movement, such as a stretch, in any one minute, were excluded from the results in the first series and only used in the preliminary analysis of the second.

The short-gestation infants were placed in the metabolism chamber and the feeding tube attached to a connector which penetrated the door in an air-tight fashion, with a 3-way tap on the outside. In order to standardise the rate of administration, for each hour between feeds, 5 minutes of feeding time were allowed; therefore, if the infant was being fed 2-hourly, the feed would be given over a period of 10 minutes. A volume of air equal to the volume of feed was extracted from the chamber simultaneously using a reciprocating pump. In 7 of these infants, measurement of $\dot{V}O_2$ in adjacent REM and NREM sleep states lasting for at least 8 minutes was possible during the 2nd postprandial hour.

In the second series $\dot{V}O_2$ of 9 healthy, term infants was measured; 3 of them were girls. Mean age was 3·5 days (range 2–5) and mean weight 3·1 kg (range 2·6–3·7). The measurements were begun 60 minutes after the end of feeding and continued for as long as the infant remained asleep.

Minute-by-minute values were obtained from the traces and these data were converted into ml O_2 consumed per minute, at standard temperature and pressure, dry. In the case of the short-gestation group, comparison was made of the differences in $\dot{V}O_2$ at four time intervals from the prefeed values using a related t test. The individual minute $\dot{V}O_2$ values of the term infants were subjected to a single mathematical 'smoothing' (A. Hyams, 1977, personal communication) based on binomial weightings, in an attempt to observe any patterns or overall trends. The minute-by-minute values were then linearly regressed for the entire period of observation, irrespective of slight movement of sleep state. Finally, a second linear regression was calculated, periods of NREM sleep and those containing significant movement having been excluded.

Results

Short-gestation infants.

Sleep states and $\dot{V}O_2$

A substantial increase in $\dot{V}O_2$ accompanied the change from NREM sleep to REM sleep (Table 2). This was diminished when no regard was taken of the direction of change, but was still significant. When REM sleep preceded NREM, the change in $\dot{V}O_2$ was not significant.

Postprandial metabolism

Because of the above observation, comparative measurements included in this series were made when the infants were in quiet REM sleep. With the exclusion of movement and NREM sleep from the periods of observation, only one of the 9 infants had continuous data for the full pre- and interfeed period (Fig. 1). Fig. 2 shows the results from eligible traces at the following times: prefeed, 0–15, 15–45, 45–60, and >60 minutes postprandially.

During the 15–45-minute period $\dot{V}O_2$ was significantly increased; the mean rise was 13%. A return to basal levels was achieved within the first hour. Rectal temperature change was greatest in the 15- to 45-minute period, with a mean rise over prefeed levels of 0·17°C (range 0–0·3). By 60 minutes postprandially this had diminished to 0·01°C (range 0–0·2).

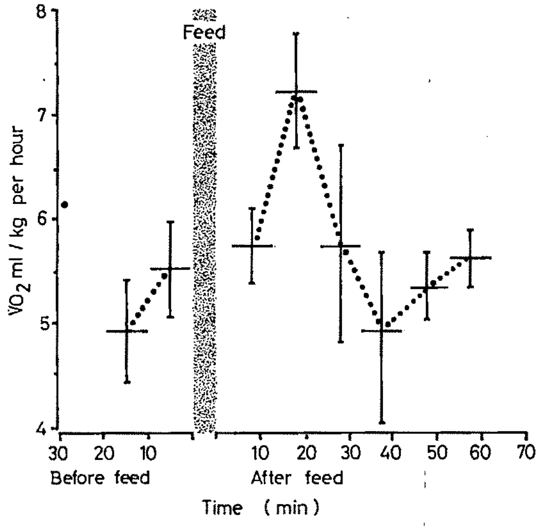

Fig. 1 *O₂ consumption of one short gestation infant who remained still, and in REM sleep throughout the pre- and interfeed periods. Only the 15- to the 45-minute period was significantly different from prefeed level (maximum difference 31%)*

Term infants.

Postprandial metabolism

Fig. 3 shows the original minute-by-minute $\dot{V}O_2$ of a term infant measured from 60 to 240 minutes after the end of a feed. Superimposed is the result of a single 'smoothing' manoeuvre. A gradual diminution of $\dot{V}O_2$ with time during each NREM sleep period was observed, as was the variability associated with movement. Visually, however, there was no obvious overall trend during the 3 hours of observation.

Details of linear regression of $\dot{V}O_2$ with time, without regard to sleep state or movement are given in Table 3. There was no significant difference in the slopes from horizontal when the group was considered as a whole. Exclusion of periods of movement and of NREM sleep did not alter the results significantly.

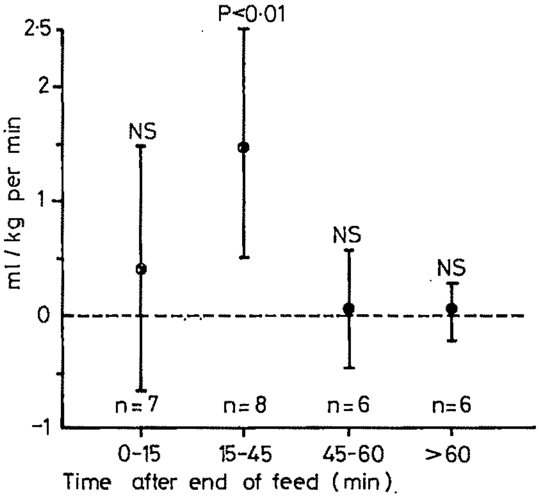

Fig. 2 *Results of pooled data from the 9 short-gestation infants. Means of the differences from the prefeed (0) levels are shown with the SDs. Only the 15- to 45-minute period is significantly different.*

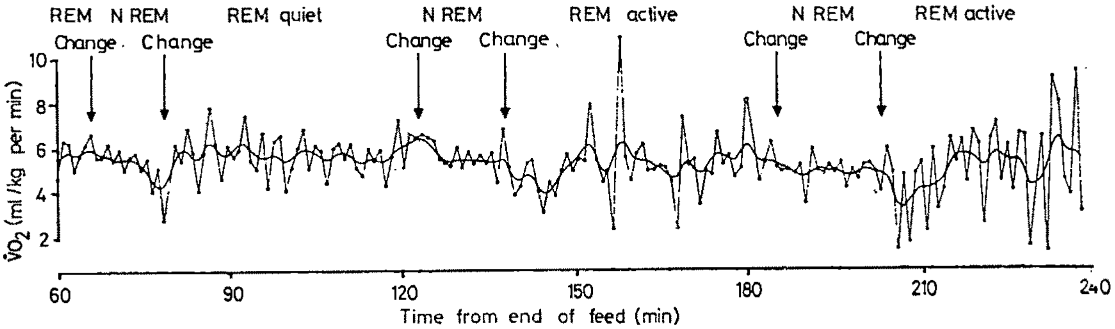

Fig. 3 *Minute-by-minute O_2 consumption ( ) of a 2·9 kg breast-fed infant aged 2 days. The result of a single smoothing (/V) is superimposed. In this case the slope value was not significantly different from zero ($B = -0·0023$)*

Table 3 *Individual results of the linear regressions of $\dot{V}O_2$ on time. A negative value of B, the slope of the regression line, represents a diminution of $\dot{V}O_2$ with time, and a positive value an increase*

The rectal temperatures showed neither significant nor consistent directional change during the periods of observation (Table 3).

Discussion

The fact that $\dot{V}O_2$ increases in REM sleep in premature infants is in keeping with the findings of Scopes and Ahmed (1966), and also in agreement with our own findings in term infants (Stothers and Warner, 1978). It is interesting that the magnitude of maximum change (15%) was considerably greater than the 6·6% rise found in the latter series, and emphasises the fact that when comparative $\dot{V}O_2$ measurements are being made over fairly short periods of time, note should be taken of sleep states.

The results from the feeding series support previous workers' findings of a rise in $\dot{V}O_2$ postprandially. From the small sample of short-gestation infants measured just before and after gavage feeding the magnitude of the rise appeared highly variable, ranging from 4 to 50% of the resting values. This large variation may have been due to several factors. The effect of age on resting metabolism is well established, but the importance of the effect of the energy content of the food, the state of nutrition, and growth rate on the size of response is less widely accepted.

Evidence that these factors are of major importance is however accumulating. In 1966 Krieger found that insensible water loss, which she used as an index of metabolic rate, increased after feeding only during periods of weight gain in infants aged between 5 and 43 months. No such increase was observed when weight was either static or decreasing. Ashworth (1969) using indirect, open-circuit calorimetry measured the effect of feeding on 8 malnourished infants aged between 10 and 36 months and reported that during the 'catch-up' phase, or period of rapid growth, the metabolic rate increased significantly. Once the growth rate had returned to normal there was no such increase. She concluded that in the case of the starved infants the classic concept of SDA did not apply and that the size of increase in metabolic rate after a meal was related to 'the energy cost of growth and, in particular, to the energy cost of protein synthesis'. This theory has now been convincingly supported by Gentz *et al.* (1976) who reported measurements of $\dot{V}O_2$ and respiratory quotient (RQ) of 5 infants aged between 2 and 11 days who were either small-for-dates or of diabetic mothers. A rise in both variables was observed after feeding, and it was suggested that the most likely cause was protein synthesis and lipogenesis. Thus the simple concept of SDA proposed by Voit (1901) as food being fuel for the metabolic fire could be made compatible with modern views if one introduces Ashworth's 'energy cost of growth' as a variable 'fanning' of the flames.

In the present studies the duration of the response was more consistent. All of the babies in the first series regained prefeed $\dot{V}O_2$ values within the first hour from the end of the feed. In general this is in agreement with Brooke's findings (O. Brooke, 1978, personal communication). Support for this observation was obtained from the term infants in whom $\dot{V}O_2$ did not diminish consistently with time, as one would expect if significant effects exceeded one hour. This is in contrast with the findings previously reported in newborn babies (Městyán *et al.*, 1969; Gentz *et al.*, 1976), and piglets (Gentz *et al.*, 1970) in which considerably longer 'recovery' periods were observed. Explanation of the apparent conflict necessitates further examination of those series.

Only group 1 of the infants of Městyán *et al.* (1969) were nursed in thermoneutrality. These preterm infants had an interfeed period of 4 hours. The ages of their 8 infants ranged from 6 to 24 days and their weights from 1300 to 2100 g. 40 to 60 ml milk were given, an amount per feed which is considerably greater than that given in the present series, although the daily volumes were approximately equal. The longer interfeed intervals and the increased volumes may explain the longer 'recovery' periods. The range of changes of $\dot{V}O_2$ was similar to our own series (11–44%), but the mean was higher (30%).

The study by Gentz *et al.* (1970) comprised fed and unfed piglets. The maximum rise in $\dot{V}O_2$ and the lengthy duration of the effect were found in the unfed group, which is not comparable with the infants in the present study, all of whom had been previously and recently fed. In his fed group, however, there was a rise of about 10%, which because of individual variation did not reach statistical significance. In addition, the peak $\dot{V}O_2$ values appear to have been reached some 30 minutes after administration of the sows' milk. The length of time taken to return to prefeed $\dot{V}O_2$ levels was not reported.

Full details of the volume and interfeed intervals of the babies in Gentz's series unfortunately were not reported (Gentz *et al.*, 1976). It is interesting to note, however, that the pattern of response was similar to that reported by Městyán *et al.* (1969), suggesting a similarity of feeding regimens; the maximum rise in $\dot{V}O_2$ occurring in the 60- to 90-minute period postprandially with a subsequent, gradual return to prefeed levels.

Our results suggest that the response to feeding is highly variable, but that in 'appropriately-fed' infants the effects should not exceed an hour. Great difficulty arises, however, in the interpretation of 'appropriate'. No firm rules of the volume or frequency with which short-gestation infants should be fed can be made from this small study. It only supports the advocates of 'a little and often'. In the healthy, term, demand-fed babies the recovery period was within an hour, suggesting that the infant knows best the appropriate volume and timing, supporting the protagonists of demand feeding.

We thank Professor K. W. Cross for encouragement and advice, Dr M. Hathorn for statistical assistance, Mr T. Barnett and Mr R. Shew for technical help, the medical and nursing staff for support, and the Sir Halley Stewart and Wellcome Trusts for financial support.

Hearing loss in very low birthweight infants treated with neonatal intensive care

SOLOMON J. ABRAMOVICH, SHEILA GREGORY, MARGARET SLEMICK,
AND ANN STEWART

Departments of Obstetrics and Paediatrics, and Royal Ear Hospital, University College Hospital and Medical School, London

SUMMARY The hearing of 111 perinatal intensive care survivors of birthweights 1500 g or less was assessed at a mean age of 6½ years (range 4–12). These 111 infants included 86% of the long-term survivors of this birthweight cared for in the newborn unit of University College Hospital, London, during the years 1966–72. All these infants were nursed in commercially available incubators for periods ranging from 2 to 80 days (mean 37) in which the mean noise threshold was 65 dB. Ten (9%) had sensory neural hearing losses, one (1%) infant had a congenital conductive hearing loss, and 21.(19%) infants had exudative otitis media with a mean loss of 25 dB. Apnoeic attacks in the neonatal period were the most significant predictors of hearing loss in these infants ($P<0\cdot05$) and an indirect serum bilirubin level of at least 170 μmol/l (10 mg/100 ml) in the neonatal period had an additive effect ($P<0\cdot05$). There was no evidence that ambient noise had affected the hearing of these very low birthweight infants.

Reports indicate that the incidence of sensory-neural hearing loss among very low birthweight infants is high (4 to 15·9%) (Campanelli *et al.*, 1958; McDonald, 1964). Douek *et al.* (1976) suggested that this might be due to damage of the cochlea by ambient noise from the incubators in which these infants are usually nursed. To support this suggestion they quoted a study by Campanelli *et al.* (1958) which showed that the mean length of stay in incubators for low birthweight infants with sensory neural loss was significantly longer than the mean for low birthweight infants without hearing loss. There were, however, other important differences between the two groups. In particular, the mean birthweight in children with sensory neural hearing loss was only 981 g, whereas the mean for the children without hearing loss was much greater—1718 g ($P<0\cdot05$).

The incidence of potentially lethal or damaging perinatal complications increases as birthweight and gestation decrease. Thus, the infants in the study of Campanelli *et al.* (1958) who had sensory neural hearing loss are much more likely to have suffered brain damaging complications than the heavier infants without hearing loss. Perinatal complications are also likely to influence the length of incubator stay. Thus it is important to investigate the potential role of all these factors in the aetiology of sensory neural hearing loss before attempting to apportion blame.

Population

During the years 1966–72, 273 infants of birthweights 1500 g or less were admitted to University College Hospital (UCH) for neonatal intensive care. 164 were born in UCH, 99 were referred from other hospitals, and 10 were admitted from home where they had been born unexpectedly. 132 (48%) of these infants survived. 129 of the surviving infants were followed up for more than 5 years, 2 were lost to follow-up, and one child died after a domestic accident at age 4 years.

Methods

The management of the infants during the perinatal period and at follow-up after leaving hospital has been described (Stewart and Reynolds, 1974;

Ear, Nose and Throat Department, King's College Hospital, London
SOLOMON J. ABRAMOVICH, senior registrar

MARGARET SLEMICK, retired audiometrician

Stewart *et al.*, 1977; Turcan *et al.*, 1977). Methods included a high standard of obstetric care, prompt resuscitation at birth and subsequently, prevention if at all possible of hypoxia, hypothermia, hypoglycaemia, hyperbilirubinaemia, and infection; and the provision of warmth and adequate nutrition.

All the children were nursed in standard, commercially available incubators until their weights were >1500 g. Noise levels in these incubators under normal working conditions in the neonatal unit were tested using a Dawe octave band sound level meter. The noise levels in 9 incubators of 4 types which had been in use in UCH for at least 10 years, including the years that the children being studied were born, varied from 58 to 72 dB on all weightings of the octave band sound level meter. The mean threshold was 65 dB sound pressure level. The mean threshold on A weighting was 62 dB, on B weighting 65 dB, on C weighting 67 dB, and D 66 dB. The noise level outside the incubators was 65–75 dB sound pressure level on all weightings.

After leaving hospital the children were seen regularly for clinical and neurological assessments, including otoscopic examination and developmental testing. Psychometric measurements were made at 3½, 5, and 8 years; these included educational and attainment tests, and assessment of motor skills for the older children. Hearing responses were elicited in the course of developmental testing, and children in whom satisfactory responses could not be obtained by age 9 months were referred for detailed testing, using 'distraction' techniques and objective hearing testing, using the posterior auricular muscle (PAM) response method (Fraser *et al.*, 1978), in the audiological unit of the Royal Ear Hospital, UCH.

Pure tone audiometry within the speech frequencies (250–8000 Hz) was tested on all children who were able to co-operate sufficiently to give a reliable response at ages ranging from 4 to 12 years. The function of pure tone audiometry was to compare the hearing of the child with accepted hearing levels for normal subjects (International Standards Organisation). Thus, a mean loss of >20 dB in the speech frequencies was considered to be abnormal. Among children unable to co-operate, usually because of other serious handicaps—such as mental retardation—the hearing threshold was evaluated using free field audiometry, the PAM response method (Fraser *et al.*, 1978), and transtympanic electrocochleography (ECOG) (Beagley *et al.*, 1974).

Results

The hearing threshold was elicited in 111 of the 129 children. Pure tone audiograms were obtained from 107 children at a mean age of 6½ years (range 4–12).

In one very retarded child the threshold was obtained with pure tone audiometry in free field, and 3 children were assessed with PAM or ECOG. No audiogram was obtained from 18 children, comprising 14 who were living abroad and 4 whose parents did not co-operate. All these 18 children had developed normal speech and were considered by their local medical practitioners, teachers, and parents to have normal hearing. In the group of 111 children in whom the hearing threshold was elicited, one child had congenital conductive hearing loss, 21 (19%) had exudative otitis media with mean hearing loss of 26 dB, and 10 (9%) had sensory neural hearing loss. Of these 10 children, 8 had bilateral losses in the speech frequencies (250–8000 Hz) which varied from 35–80 dB (mean 51). Four of the 8 were seriously handicapped by their hearing loss and required special education. The other 4 were able to compensate for the loss with hearing aids and remedial help, and attended normal schools. Two other children had unilateral losses, including one with a loss of 70 dB at 8000 Hz only, but both these children had hearing which was adequate to perceive speech without difficulty.

The distributions of birthweight, period of gestation, sex, single or multiple pregnancy, place of birth, or method of delivery were the same for children with or without sensory neural hearing loss (Tables 1 and 2). Records for length of stay in the incubator were only available for the 56 infants, including 7 with sensory neural hearing loss, who were born in the years 1968–69 and 1971–72. (Records

for the other years were destroyed in a flood during the preparation of these data.) There was no significant difference between the length of stay for the children with or without sensory neural hearing loss among the 56 children ($P<0{\cdot}1$) (Table 2).

The incidences of perinatal complications in the children with or without sensory neural hearing loss are shown in Table 3. Two complications—apnoeic spells in the neonatal period that were sufficiently severe to require treatment with mechanical ventilation, and a serum bilirubin level of at least 170 µmol/l in the neonatal period were present more often in children with sensory neural hearing loss than in those without. However, the difference was only significant in the children who had apnoeic spells ($P<0{\cdot}025$). The mean maximum serum bilirubin level among the 6 jaundiced children with sensory neural hearing loss was greater than the mean among the 28 jaundiced children without hearing loss, but this difference was also not significant ($P<0{\cdot}2$).

Only one (10%) of the 10 children with sensory neural hearing loss had cerebral palsy. This incidence did not differ significantly from that for the 101 (4%) children without hearing loss.

All the children in the study had a psychological assessment at 3½ years. To accommodate the varying skills of such children, one of three different tests was chosen. It was, therefore, not possible to calculate mean scores, but the distribution of the SD grouping was significantly lower in the 10 children with sensory neural hearing loss than in those without ($P<0{\cdot}05$). 55 of the children were aged at least 8 years and were assessed on the (WISC) IQ scale. There were highly significant differences between the means of the performance, verbal, and full-scale scores in this test for the 6 children with sensory neural hearing loss and for the 49 without such loss ($P<0{\cdot}001$) (Table 2). This indicated an overall depressed level of functioning for the children with sensory neural hearing loss and suggested that these children may have suffered additional cerebral

insults. This was also suggested by the finding that 7 of the 10 children with sensory neural hearing loss were receiving extra help in school for such difficulties as distractability, overall delay, and manual control, as well as those due to their hearing loss. Data on the 10 children with sensory neural hearing loss are summarised in Table 4.

To investigate the aetiology of sensory neural hearing loss in this group of children, analysis of variance with stepwise regression was carried out using 29 social, obstetric, and perinatal variables. 25 (22%) of the 29 variables contributed significantly to the sensory neural hearing loss. The most important contribution (5% of the variance) was made by apnoeic spells occurring in the newborn period; this variable was the only one that made a significant independent contribution ($P<0 \cdot 05$). Four other variables—mechanical ventilation, jaundice (defined as a serum bilirubin $\geqslant$ 170 μmol/l), duration of incubator stay, and method of feeding—made significant additional contributions. However the treatment variables—mechanical ventilation, duration of incubator stay, and method of feeding—were significantly correlated with many of the illness variables. In order to try to separate the effects of the methods themselves and the conditions for which they were given, the variables were grouped into those concerning the antenatal period, perinatal illness, or treatment, and the regression was repeated. On this occasion, only 10 of the 11 variables concerning perinatal illness proved to be significant predictors of sensory neural hearing loss, and together these contributed 12% of the variance. As in the first regression, apnoeic spells occurring in the neonatal period was the most important variable, and the only one to make a significant independent contribution to the variance. Jaundice was the only variable to make a significant addition. Thus, it appears that perinatal illnesses, particularly those known or likely to have caused hypoxia in the newborn period including apnoea, were the most important factors associated with sensory neural hearing loss in this group of very low birthweight infants; jaundice may have had an additive effect.

Discussion

The incidence of sensory neural hearing loss was 9% (10 children) in this group of 111 children of birthweights 1500 g or less. All these children had survived after admission to the neonatal unit of UCH during the years 1966–72, when modern methods of perinatal management were being developed. Among the 10 affected children only 4 (4% of the whole group) were seriously handicapped by hearing impairment; 4 (4%) had moderate losses for which they were able to compensate by wearing hearing aids and receiving extra help within normal schools; and 2 (2%) had hearing which was adequate for perceiving speech without difficulty (Table 4). These figures are the same as those reported by Stennert *et al.* (1977) for a group of children of birthweights 2500 g or less, born 2 years earlier. Reports of other recent follow-up studies of low birthweight infants do not give sufficient data to allow comparison, although Davies and Stewart (1975) reviewing reports of such children suggested that the incidence of moderate to severe hearing impairment among recent very low birthweight survivors may be less than 2%.

Earlier workers reported incidences of about 10–12% of sensory neural hearing loss or moderate to severe deafness in prospective studies of very low birthweight infants (Drillien, 1961; Lubchenco *et al.*, 1963). Other reports gave incidences of 4–15% (Campanelli *et al.*, 1958; McDonald, 1964) for babies of short gestations and very low birthweights, but these figures were either based on selective assessments or were derived from selected groups of deaf children. Thus it is difficult to know if they represent maximum or minimum estimates.

These reports all concerned children who were born at least 20 years ago when little was known or understood about the hazards which low birthweight infants have to overcome in order to survive. Survival rates were low and the incidence of serious handicaps among the survivors was high, suggesting that many had sustained brain damage. What is more, few were nursed in incubators (Douglas and Gear, 1976), and of these, only those born during the 1950s were likely to have been exposed to noise from incubator motors. Incubators in general use before that date usually were heated by manually filled hot water tanks (Hey, 1974). In contrast, all intensive care survivors are likely to have been nursed in potentially noisy motor-driven incubators. In spite of this, the incidence of sensory neural hearing loss among these recent survivors was not greater than among the earlier born infants.

Schulte *et al.* (1977) and Stennert *et al.* (1977) have shown, among low birthweight infants (<2500 g), that 'nonoptimal' perinatal conditions and duration of incubator care both correlate with later hearing defects, but they were unable to separate the two factors. They concluded that noise levels of currently used incubators do not cause sensory neural hearing loss in otherwise healthy preterm infants, regardless of the duration of incubator care, but they were unable to ascertain whether incubator noise may contribute to the excess of hearing deficits noted in infants in whom the perinatal period was 'nonoptimal'.

None of the audiograms of the children with sensory neural hearing loss in this study showed a notch at 4000 Hz which is considered to be characteristic of damage to the cochlea due to long-term noise exposure (Chadwick, 1971). All the audiograms either had a gradual fall of threshold towards the high frequencies, or an abrupt loss at 8000 Hz only. Losses of this kind are generally associated on clinical grounds with anoxic insults or jaundice (Fisch and Osborn, 1954; Fisch, 1955; Fenwick, 1975).

Earlier workers (Johnsen, 1952; McDonald, 1964) suggested that anoxia was probably responsible for the sensory neural hearing loss they observed among low birthweight infants. In our own study, in addition to audiograms typical of this type of insult, or jaundice, perinatal illnesses, particularly those likely to have caused hypoxia in the neonatal period, significantly predicted sensory neural hearing loss; and a serum bilirubin level >170 μmol/1 added significantly to the prediction.

This study shows that sensory neural hearing loss in very low birthweight infants is probably caused by hypoxia in the neonatal period and that jaundice may have an additive effect. We found no evidence to support the suggestion that ambient noise caused by incubator motors contributed to sensory neural hearing loss in these infants all of whom were nursed in commercially available incubators. However, as monitoring devices using noise signals are being used with increasing frequency in the management of such newborn babies, attention should be paid to ambient noise levels to ensure that potentially damaging levels are not exceeded.

We thank the doctors, nurses, and members of the audiological staff in the Paediatric Department and Royal Ear Hospital of University College and other hospitals for help, in particular Mr Graham Fraser, Mr Jonathan Hazell, and Professor E. O. R. Reynolds; also Miss Anthea Drake for rescuing the incubator treatment records, and Miss Wendy Galbraith for persuading us to embark on this study.

S.G. and A.S. are supported by a grant from the Department of Health and Social Security.

1028 neonatal electrocardiograms

R. W. A. JONES, C. SHARP, L. R. RABB, B. R. LAMBERT, AND D. A. CHAMBERLAIN

Royal Sussex County Hospital, Brighton

SUMMARY Electrocardiograms were recorded from 1028 (99·4%) of 1034 consecutively born babies on the 1st or 2nd day of life. Abnormalities of cardiac rhythm or conduction were found in 49 (4·8%) babies. 17 babies had single or multiple premature beats during the recordings, and 7 babies showed sudden increases in R-R interval possibly due to sinoatrial node dysfunction. One baby had pre-excitation, 6 babies had superior QRS axes with clinically normal hearts, and 17 had sinus or junctional bradycardia of <80 beats/min. One baby had an incessant reciprocating tachycardia and subsequently required digoxin for heart failure. Continuous 24-hour ECG monitoring in 25 babies with abnormalities of the screening ECG, and 25 babies without such abnormalities, failed to show any additional tachyarrhythmias or bradyarrhythmias warranting treatment. In view of the uncertain clinical significance of many neonatal arrhythmias and cardiac conduction disorders, more information concerning their natural history and relationship to sudden unexpected death in infancy is needed before recommending that neonatal ECG screening be generally adopted.

Investigation of the neonatal electrocardiogram by both standard and continuous recording techniques has revealed a high incidence of asymptomatic arrhythmias and cardiac conduction disorders in the newborn period (Michaëlsson, 1959; Morgan *et al.*, 1965; Morgan and Guntheroth, 1965; Urbach *et al.*, 1965; Välimäki, 1969, 1971; Välimäki *et al.*, 1974). The importance of arrhythmias as a cause of infant morbidity has been increasingly recognised (Engle and Ehlers, 1973; Ferrer, 1977), while Southall *et al.* (1976, 1977) have drawn attention to potentially life-threatening ECG abnormalities in otherwise healthy newborn infants. These workers have suggested a link between such abnormalities and sudden unexpected death in infancy, and that an ECG performed as part of the routine neonatal examination might identify some babies at risk (Keeton *et al.*, 1977). In the present study we assessed the incidence of arrhythmias and cardiac conduction disorders, together with the feasibility of routine neonatal ECG screening, by performing a 6-lead ECG on a large number of consecutively born infants from a well defined neonatal population.

Methods

Six-lead ECGs (leads I, II, III, aVR, aVl, and aVF; Siemens Cardiostat Electrocardiograph) were performed on 1028 (99·4%) of 1034 babies born consecutively between 1 May and 21 September 1977 at this hospital. During 1977 88% of all deliveries in the Brighton health district (population 300 000) took place in the maternity department of this hospital. The recordings, which included a 10-second rhythm strip (lead II), were performed by one of two residents at the end of the routine neonatal examination on the 1st or 2nd day of life while the baby was resting or feeding in his mother's arms. Some babies were studied in the special care baby unit. Each mother had previously been issued with a typewritten explanatory note. Three babies who died within 7 hours of birth, 2 normal babies, and one baby transferred elsewhere at 2 hours for treatment of a large diaphragmatic hernia were not studied. Babies in whom a heart murmur was heard had a full 12-lead ECG performed.

24-hour ECG tape recordings (Medilog Cassette Recorder, Oxford Electronics Co. Ltd) were performed on 25 babies with abnormalities of the screening ECG, and on a further 25 control babies. These tapes were analysed on a playback system and computerised arrhythmia detector (Pathfinder, Reynolds Medical Electronics Ltd).

Results

Positive findings are summarised in the Table.

Premature beats. These were found in 17 (1·7%) babies, and were atrial in 12, ventricular in 3, and both atrial and ventricular in 2. They were multiple in 12 cases. 24-hour recordings, performed in 14 babies, showed that premature beats accounted for between 0·4 and 5% of all beats during a 24-hour period. Two babies had 2 consecutive ventricular premature beats, one baby had multifocal ventricular premature beats, and one baby had periods of atrial bigeminy. In 4 babies with atrial premature beats on the initial ECGs, 24-hour recordings showed sudden increases in R–R interval suggesting sinoatrial node dysfunctions. Three of the tapes were normal. No episode of ventricular or supraventricular tachycardia was seen.

Sinoatrial node dysfunction. Many infants showed sinus arrhythmias. Seven showed sudden increases in R–R interval unrelated to respiration and possibly indicating sinoatrial node dysfunctions (Fig. 1). Four of these babies had 24-hour tapes; all showed frequent sudden increases in R–R interval, one showed multiple atrial premature beats, and one showed episodes lasting up to 10 seconds of sinus bradycardia with junctional escape beats at an interval corresponding to a rate of 48 beats/min (Fig. 1).

Pre-excitation. One baby had a short PR interval and delta wave suggesting pre-excitation, and this persisted at follow-up 6 months later. Repeated 24-hour tapes failed to show any clear episodes of supraventricular tachycardia.

Reciprocating tachycardia. One baby, noted to have an irregularity of the fetal heart from the 30th week of gestation and a persistent fetal tachycardia during labour, was found at birth to have a continuous tachycardia of 210 beats/min (Fig. 2). ECG showed inverted P-waves in leads II, III, and aVF, indicating retrograde atrial activation; subsequent recordings showed intermittent brief returns to sinus rhythm. 24-hour tape recordings showed in addition multiple interpolated ventricular premature beats. The P-wave vector and decrease in sinus cycle lengths preceding each initiation of the tachycardia distinguished this abnormality as an 'incessant' or 'permanent' reciprocating tachycardia (Coumel, 1975). It persisted at a rate of 170–210 beats/min, and at age 4 months heart failure necessitated digitalisation. He subsequently returned to sinus rhythm and has remained well.

Table *Positive findings in 1028 neonatal electrocardiograms*

Abnormalities	*No. of babies*
Premature beats (n=17)	
Atrial	12
Ventricular	3
Both	2
Sinoatrial node dysfunction	7
Pre-excitation	1
Reciprocating tachycardia	1
Bradycardia <80 beats/min (n=17)	
Sinus	13
Junctional	4
Superior QRS axis 0 to −120	6
Total	49
Other findings	
Superior QRS axis −120 to −150	15
Variation in P wave shape in lead II	65

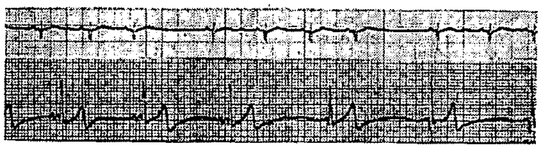

Fig. 1 *Sinoatrial node dysfunction. Upper trace: lead II showing sudden increase in R–R interval. This is preceded by a progressive decrease in P–P interval suggesting 2nd degree (Wenckebach) sinoatrial block. Lower trace: 24-hour tape of same infant showing sinus bradycardia with junctional escape beats at an interval corresponding to a rate of 48 beats/min.*

Sinus and junctional bradycardia. Heart rates of <80 beats/min were seen in 17 (1·7%) babies, the

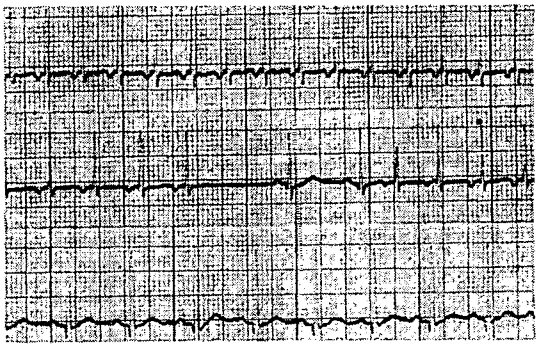

Fig. 2 *Incessant or permanent reciprocating tachycardia. Upper trace: lead II on day 1 showing tachycardia of 210 beats/min, the inverted P–waves indicating retrograde atrial activation. Middle trace: day 2 showing brief return to sinus rhythm followed by recurrence of the tachycardia, the premature impulse showing a slightly altered QRS configuration due to aberrant conduction. Lower trace: sinus rhythm after digitalisation at age 4 months.*

slowest rate being 60. The bradycardia was sinus in 13 cases, and junctional in 4. 24-hour tapes, performed in 5 of these babies, did not show any bradycardias of <60 beats/min, nor did they reveal additional arrhythmias.

Superior QRS axis. The frontal plane QRS axis was 0 to −120 in 6 babies, none of whom had any clinical evidence of structural heart disease. Of 4 of these babies followed up, only one had a persistently superior axis at age 3 months.

Other screening ECG findings. The QRS axis was between −120 and −150 in 15 babies, all of whom had clinically normal hearts. Variation in P–wave shape in lead II was observed in 65 (6·4%) babies (Fig. 3) and was associated with the occurrence of atrial premature beats ($\chi^2 = 45{\cdot}7$, $P < 0{\cdot}001$).

Control 24-hour tapes. These were performed in 25 babies whose screening ECGs had been normal. Sinus rates varied between 60 and 240 beats/min. Two babies showed occasional atrial premature beats, and one baby had 2 isolated ventricular premature beats. Two babies had sudden increases in R–R interval, suggesting sinoatrial node dysfunctions. One preterm baby had repeated episodes of sinus bradycardia at a rate of 50 beats/min lasting up to 10 seconds. No sustained tachyarrhythmias or bradyarrhythmias were seen.

No significant association was found between any ECG abnormality and preterm delivery, birthweight, birth asphyxia, or neonatal respiratory illness. Except for one baby who developed heart failure due to reciprocating tachycardia (Fig. 2), there was no clinical disturbance in any baby with an abnormal ECG, and none had any evidence of structural congenital heart disease.

One baby in the study died suddenly and unexpectedly at home at age 6 months. She had been born at 35 weeks' gestation, and the screening ECG, apart from showing tall P-waves in lead II suggesting right atrial hypertrophy, was normal. No cause of death was found at necropsy and detailed histology of the cardiac conducting tissue (Dr R. Anderson, Brompton Hospital) was normal.

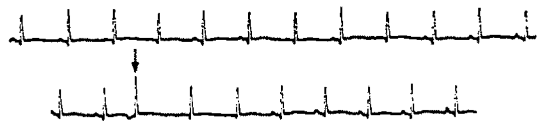

Fig. 3 *Variation in P–wave shape in lead II. Note suppression of sinoatrial node activity after atrial premature beat (arrowed).*

Discussion

Although the present study confirms that arrhythmias and cardiac conduction disorders may be detected by routine ECG screening in otherwise healthy newborn infants, the relationship of these abnormalities to subsequent morbidity remains uncertain. Both premature beats and pre-excitation may occur as transient phenomena in early infancy (Friedman *et al.*, 1969; Välimäki, 1971), but may also be associated with tachyarrhythmias (Moene and Roos, 1973; Silver *et al.*, 1973; Southall *et al.*, 1977), although in the present study we were unable to document any such association using either standard ECGs or 24-hour recordings. We also failed to detect any tachyarrhythmias or bradyarrhythmias requiring treatment in 25 control babies studied by 24-hour taped ECGs. Although the range of ECG abnormalities was similar, the incidence of potentially serious arrhythmias was therefore low compared with that found by Southall *et al.* (1976, 1977). One baby, however, developed heart failure due to an incessant reciprocating tachycardia (Fig. 2), an arrhythmia previously described in infancy and shown by intracardiac electrophysiological studies to be due to a re-entry mechanism in the region of the atrioventricular node and upper His bundle (Coumel, 1975). This arrhythmia was detected antenatally, underlining the importance of considering the possibility of fetal arrhythmia when persistent fetal tachycardia or heart irregularity is noted during pregnancy or labour.

Supraventricular tachycardia is a well documented cause of heart failure in the perinatal period (Radford *et al.*, 1976), and has also been found in some cases of 'near miss' sudden unexpected death in infancy (Keeton *et al.*, 1977). The significance of bradyarrhythmias is less certain, and in many cases occurs secondarily to apnoea (Girling, 1972) or increase in vagal tone (Cordero and Hon, 1971), junctional escape rhythms reflecting the relatively high intrinsic firing rates of the subsidiary pacemaker tissues in this age group. Sinus arrhythmia and sudden changes in heart rate are common in the newborn, especially when preterm, and may reflect autonomic immaturity (Lipton *et al.*, 1965; Church *et al.*, 1967). The abrupt increases in R-R interval noted in babies in the present study may have a similar aetiology, but might alternatively be a manifestation of dysfunction of the sinoatrial node, especially in those cases associated with episodes of sinus or junctional bradycardia (Fig. 1). Although sinoatrial node dysfunction has recently been recognised as a cause of syncopal attacks in older children even in the absence of structural heart disease (Scott *et al.*, 1976), its significance in the newborn period is uncertain. Variation in P-wave shape (Fig. 3) has previously been ascribed in adults to variability in the site of formation and subsequent atrial conduction of the sinoatrial node impulse (Brody *et al.*, 1967). This phenomenon in the newborn, together with the occurrence of sinoatrial node dysfunction and the tachycardia-bradycardia syndrome (Southall *et al.*, 1977), supports the concept of continuing functional maturation of the sinoatrial node in early postnatal life. Confirmation of this hypothesis awaits more detailed study of sinoatrial node function in this age group.

A superior QRS axis is often associated with structural congenital heart disease, most frequently an atrioventricular canal or ventricular septal defect in the acyanotic infant (Shinebourne *et al.*, 1974). Only one baby in the present study had a persistently superior QRS axis which, in the absence of any clinical evidence of structural defects, probably represents isolated left anterior hemiblock.

Sudden unexpected death in infancy represents a spectrum of diseases and social situations, and Emery (1977) considers that only a few, perhaps 10%, are likely to be due to cardiac arrhythmias. From this figure, it has been estimated that more than 40 000 neonates would have to be screened before a significant association could be shown (D. Southall, personal communication). In addition, it is not certain that an infant who dies suddenly from cardiac arrhythmia will necessarily have any abnormality detected by a screening ECG in the neonatal period. It nevertheless seems reasonable to investigate cases of 'near miss' sudden unexpected deaths with a standard ECG and, if possible, with 24-hour ECG combined with respiratory tape monitoring, the latter in order to assess the incidence and timing of apnoea in babies with bradyarrhythmias. The provision of *routine* neonatal ECG screening, however, together with 24-hour tape recording and analysis, gave our neonatal department a sizeable additional work load and also generated some maternal anxiety. Until there is more information concerning the natural history of neonatal ECG abnormalities and their relationship to sudden unexpected death in infancy, it is premature to recommend the general adoption of neonatal ECG screening.

We gratefully acknowledge the help of Mrs Stephanie Baker and Dr J. Cree.

Sinusoidal heart rate rhythms in severe neonatal hypoxia

MARK McC. REID, J. JENKINS, AND GARTH McCLURE

Special Care Baby Unit, Royal Maternity Hospital, and Jubilee Maternity Hospital, and Department of Child Health, Queen's University, Belfast

SUMMARY Sinusoidal heart rate traces were detected in 8 patients, 6 of whom died; the 2 survivors showed evidence of gross cerebral damage. It is felt that the origin of the sinusoidal curve is probably central and reflects loss of central control of heart rate.

Continuous monitoring of the fetal heart rate through labour has led to the detection of abnormal heart rate patterns indicative of fetal distress. One significant pattern detected by Baskett and Ko (1974) and Manseau *et al.* (1972) was the sinusoidal heart rate pattern, characterised by slow regular wave forms in the fetal heart rate. This pattern in the neonatal period was also described by Ekert and Schenk (1974). In all reports the appearance of this pattern was associated with a poor prognosis. We wish to report our observations on sinusoidal heart rate patterns seen in 8 infants in a one-year period in two special care baby units in Belfast.

Patients and methods

During a period of one year all ill newborn infants receiving intensive care in our units in Belfast were monitored using cardiorespirographs (Corometrics 512 and Hewlett-Packard Cardio-Respiratory Monitor 78250A). These monitors detect successive R-waves on the electrocardiograph and give an instantaneous heart rate, both as a digital read-out and on a paper trace. The respiratory rate and amplitude are detected, by an impedance method, by two electrodes placed laterally on the chest wall.

During the period under review 130 infants were monitored. The infants suffered from a variety of conditions including idiopathic respiratory distress syndrome (IRDS), severe congenital heart disease, rhesus haemolytic disease, and apnoeic spells of prematurity. The clinical data of the 8 patients with sinusoidal heart rate traces are given below.

Case 1. A baby boy delivered by caesarean section in a peripheral hospital at 43 weeks' gestation with a birthweight of 4600 g. Caesarean section was performed because of delay in labour which had lasted 36 hours. Meconium-stained liquor had been passed and fetal bradycardia had occurred intermittently in the 24 hours before delivery. The Apgar score was 2 at five minutes and spontaneous respirations were not attained until age 10 minutes. The infant then developed a series of apnoeic spells and was transferred at age 6 hours. On admission the infant was hypotonic and had periodic apnoeic spells. Six hours later convulsions developed which were then treated with intravenous diazepam. In spite of this the infant developed further convulsions and became increasingly hypertonic and died at age 3½ days. Necropsy showed cerebral softening and oedema but with no haemorrhage or significant abnormalities of other organs.

Case 2. A baby boy with a birthweight of 3600 g, delivered by forceps in a peripheral hospital. The Apgar score was 3 at five minutes and regular respirations were not established until 45 minutes despite active resuscitation. The infant was transferred and admitted to our unit at age 11 hours. At that time he was shocked, cyanosed, and hypoventilating. He was hypotonic and developed increasingly frequent apnoeic spells and died at age 2 days. Necropsy showed cerebral oedema and also subarachnoid, subdural, and pulmonary haemorrhage.

Case 3. A baby girl weighing 3500 g. Delivery was by Kielland's forceps for occipito-posterior position and abruptio placenta at term. Apgar scores were 2 and 4 at two and five minutes respectively. Active resuscitation was carried out but spontaneous

GARTH MCCLURE, consultant paediatrician
J. JENKINS, research fellow

respirations were not attained until 30 minutes. During the next 24 hours the baby became hypertonic and developed convulsions associated with bradycardia, apnoea, and cyanotic attacks. CSF was evenly blood stained. Spontaneous recovery occurred and the infant survived but suffers from microcephaly, spastic quadriplegia, salaam attacks, and gross developmental delay.

Case 4. A baby boy weighing 2900 g at term by normal delivery. Fetal distress had occurred during labour and the infant's Apgar scores were 4 and 2 at two and five minutes. During the first 4 days of life he was deeply unconscious and suffered from convulsive episodes and occasional apnoeic spells. Tone was variable, being initially hypotonic and then hypertonic. The infant survived but is now microcephalic with salaam spasms and pronounced hypotonia. There is also gross developmental delay.

Case 5. A baby boy born at 35 weeks' gestation by normal delivery, with a birthweight of 2700 g after spontaneous onset of preterm labour in a peripheral hospital. The infant's condition was satisfactory at birth but he then developed IRDS which was confirmed by chest *x*-ray. He was therefore transferred to one of our units at 20 hours of age. On examination he was severely ill, and cyanosed in 100% oxygen with an arterial PO_2 of 17. The pH was 6·89 and Pco_2 was 132. The infant was intubated and received intermittent positive pressure ventilation (IPPV), but died one hour later aged 21 hours. Necropsy showed evidence of pronounced pulmonary atelectasis and also subarachnoid haemorrhage.

Case 6. A baby girl born by normal delivery at 29 weeks' gestation, birthweight 1300 g, after spontaneous onset of labour. Apgar scores were 1 at five and 2 at ten minutes. In spite of active resuscitation the infant remained very ill with intermittent apnoeic spells and convulsions. CSF was evenly blood stained and the fontanelles were distended and tense, suggesting intracranial haemorrhage. The infant developed bronchopneumonia and died aged 4 days. Unfortunately consent for necropsy could not be obtained.

Case 7. A baby girl born by assisted breech delivery at 29 weeks' gestation with a weight of 1130 g after spontaneous onset of preterm labour. Apgar score was 4 at two minutes and the baby rapidly developed respiratory distress. On admission to the special care baby unit she was noted to be anaemic with a haematocrit of 40. The infant was treated with IPPV, blood transfusion, and correction of acidosis, but she failed to respond to treatment and died aged 6 hours 20 minutes. Necropsy showed a small intraventricular haemorrhage and pronounced pulmonary atelectasis.

Case 8. A baby boy delivered at 28 weeks' gestation after antepartum haemorrhage and breech delivery. The birthweight was 1080 g, Apgar score was 1 at two minutes. Spontaneous respirations were not established and the baby was treated with IPPV; however, he failed to respond to treatment and died aged 18 hours. Necropsy showed pronounced pulmonary atelectasis, a small pulmonary haemorrhage, and subarachnoid haemorrhage.

These clinical features together with a description of the sinusoidal patterns are shown in the Table.

All 8 infants demonstrated a sinusoidal heart rate. Cases 4 and 8 (Figs 1 and 2) are shown as examples. The frequency of the sinusoidal curve varied in the infants from once every 30 seconds to once every

Table *Clinical features and sinusoidal heart rate patterns in 8 infants*

			Duration	*Frequency (min)*	*Rate/min*	
1	4600	Asphyxia	3 h	3½	110–130	Died 3½ days. Necropsy: cerebral oedema and softening
2	3600	Asphyxia	40 min	2½	120–180	Died 2 days. Necropsy: subarachnoid and subdural haemorrhage
3	3500	Asphyxia	4 h	1	140–150	Lived. Microcephaly, epilepsy, and spastic quadriplegia
4	2900	Asphyxia	48 h	1½	90–120	Lived. Microcephaly, epilepsy, and hypotonia
5	2740	IRDS	8 min	1	110–150	Died 21 hours. Necropsy: atelectasis, subarachnoid haemorrhage
6	1300	Asphyxia, bronchopneumonia	12 h	½	130–150	Died 4 days. No necropsy. Intraventricular haemorrhage and bronchopneumonia
7	1130	Asphyxia, IRDS	35 min	1	60–120	Died 6 hours. Necropsy: atelectasis, intraventricular haemorrhage
8	1080	Asphyxia, IRDS	8 min	1¼	105–140	Died 18 hours. Necropsy: atelectasis, subarachnoid haemorrhage

3½ minutes and the amplitude from 10 to 60 beats/min. None of the remaining 122 infants who were monitored showed sinusoidal heart rate rhythms. 14 of these infants died, of whom 4 showed evidence of cerebral disease at necropsy but had not exhibited the sinusoidal curve patterns during life. The remaining infants died of extreme prematurity, with or without IRDS, or from congenital malformations. Of the 108 babies who were monitored and survived and who did not show sinusoidal heart rate patterns, none to date has shown evidence of neurological impairment although the follow-up period has been short, most of these infants still being under one year.

Discussion

Sinusoidal heart rate rhythms can clearly be distinguished from other heart rate patterns seen in the neonatal period as Figs 3 and 4 clearly show. Previous authors have noted that this pattern is associated with a grave prognosis, and all 8

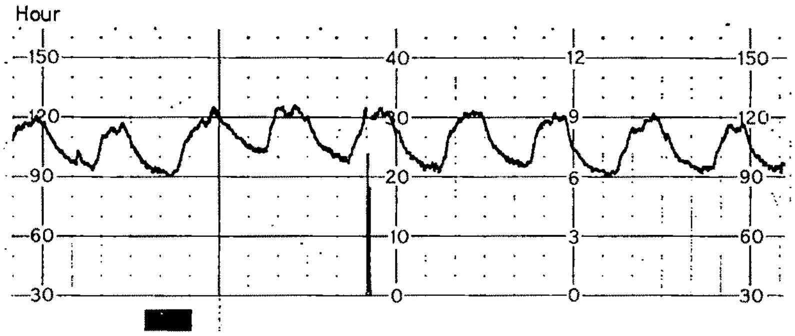

Fig. 1 *Vertical axis heart rate. Horizontally each major dark line represents a 6 min-interval.*

infants in whom we have seen this pattern have either died or have had gross residual cerebral damage. Other heart rate abnormalities, such as decreased heart rate variation, have been seen in children with brain damage and it is claimed that it may be considered a clinical criterion of brain death (Kero *et al.*, 1978). However, it must be stressed that the total observation of the sinusoidal heart rate pattern is extremely limited and many further observations would be needed to confirm its prognostic significance.

The origin of the sinusoidal curve is in some doubt. Heart rate deceleration may occur in response to a primary respiratory event as we would expect in the current apnoeic episodes. Valbona *et al.* (1965) studied adults with decerebrate states and described similar patterns with prominent waves of acceleration of heart rate rhythm followed by rebound deceleration. These waves coincided with each deep breath or with the onset of periodic breathing. Guilleminault *et al.* (1977) described cardiac arrhythmias in adults with apnoeic spells and severe CNS disease. In several of our patients the sinusoidal wave pattern was associated with recurrent regular apnoeic spells. However, in our cases there was no fixed relationship between the occurrence of apnoea and cardiac deceleration, as 3 of our 8 patients were receiving IPPV at the time when the sinusoidal heart rate pattern was seen. We feel that in these 3 cases at least, the sinusoidal heart rate pattern is unlikely to be a primary respiratory event and is more probably central in origin and may reflect a lack of central control of cardiac rhythm.

Sinusoidal patterns could also possibly be a primary cardiac phenomenon reflecting either conduction defects or a diseased myocardium. Cardiac arrhythmias have been reported in fetuses and infants during hypoxic stress but unfortunately in none of our patients did we obtain either direct electrocardiographic traces or cardiac enzyme studies. These patterns appear to have a grave prognosis, but as there is little experience we would urge caution in their interpretation, and we hope that there will be many further observations before any conclusions are made and the patients treated accordingly.

We thank all the junior medical staff and nursing staff for their careful record keeping and assistance in the collection of these records. J.J. is in receipt of a fellowship from DHSS, NI.

Breath hydrogen test for detecting lactose malabsorption in infants and children

Prevalence of lactose malabsorption in Japanese children and adults

OSAMU NOSE, YOSHIHIKO IIDA, HIROSHI KAI, TOKUZO HARADA,
MINORU OGAWA, AND HYAKUJI YABUUCHI

SUMMARY The breath hydrogen test (BHT) was adapted for use in young infants and children. The diagnostic criterion of sugar malabsorption in the BHT was determined by oral administration of 0·5 g/kg of unabsorbable sugar (lactulose) to 21 healthy infants and children. A maximum increase in breath hydrogen $>0{\cdot}05$ ml/min per m^2 was observed in all subjects. A good correlation between results by the BHT and by the ordinary lactose tolerance test was obtained after oral administration of 2 g/kg lactose to 21 healthy infants and children, 2 congenital lactase-deficient infants, and 7 adults.

Using this test, 80 healthy Japanese infants and children (aged between one month and 15 years) and 18 adults were examined for lactose malabsorption after a dose of 1 g/kg lactose. All infants and children under 2-years old absorbed lactose completely. The incidence of lactose malabsorption was 30% in 3-year, 36% in 4-year, 58% in 5-year, and 86% in 6-year-old children, 85% in schoolchildren, and 89% in adults. Thus the incidence of lactase deficiency gradually increases with age from 3 years, and about 90% of all normal Japanese adults are lactase-deficient.

At birth, humans have abundant lactase activity in the small intestine but, in most ethnic groups, there is a pronounced decrease in lactase activity during early childhood (Huang and Gayless, 1967; Johnson *et al.*, 1977). The definitive diagnosis of lactase deficiency requires the collection of biopsy specimens from the small intestine and demonstration of decreased lactase activity therein. Attempts have therefore been made to develop indirect methods for detecting lactase deficiency. Tolerance tests, although commonly used for this purpose, are influenced by many factors—such as, the rate of gastric emptying and intermediary glucose metabolism. In addition, these tests need a large amount of lactose and therefore give no information on the ability of the intestine to absorb smaller, more physiological quantities. Moreover, the results are often unreliable (Krasilnikoff *et al.*, 1975).

Recently, many investigators have shown that the breath hydrogen test (BHT) (change in the concentration in the breath of hydrogen formed by bacterial metabolism of unabsorbed lactose in the colon) is a simple, accurate, and sensitive indirect test for lactase deficiency in adults (Levitt, 1969; Bond and Levitt, 1972; Newcomer *et al.*, 1975). There have been only a few reports of this test on children under 5 years (Maffei *et al.*, 1977).

We report the application of this test in children, of from one month old upwards, and in adults to determine the incidence and age of onset of lactase deficiency in Japanese children.

Subjects and methods

Subjects. Hydrogen excretion was studied in 80 healthy children (between one month and 15 years old), 2 infants with congenital lactase deficiency (diagnosed by per-oral intestinal biopsy), and 18 normal adults (between 20 and 50 years old). Of the

80 children, 19 were infants (between one and 12 months old), 42 were preschool children (between 2 and 6 years old), and 19 were schoolchildren (between 7 and 15 years old). Informed consent was obtained from the adults and the children's parents.

Methods. The ability of the colonic flora of infants to produce H_2 during lactose fermentation was studied using faecal homogenates as described by Bond and Levitt (1972). Fresh faecal specimens (2 g) from 50 infants (15 newborn infants feeding with breast milk, 6 newborn babies with formula, 25 infants with formula, and 4 children) were homogenised in 4 ml of 0·10 mol/l phosphate-buffered saline (pH 7·0). All infants examined were healthy and not receiving treatment with antibiotics. The homogenates were placed in a series of 10 ml test-tubes and 1 ml 1·25% (mass/vol.) lactose solution was added to each. The tubes were mixed, sealed with rubber stoppers, and placed in a water bath at 37°C. A needle attached to a 50-ml syringe was inserted through the rubber stopper. After one hour, the tubes were vigorously stirred, and the gas in each tube was displaced into the syringe by injecting water into the test-tube through a second syringe. The concentration of H_2 was determined by gas chromatography.

Respiratory H_2 excretion

The subjects were starved overnight, and then the rate of respiratory H_2 excretion was determined at 0, 1, 2, 3, and 4 hours after carbohydrate loading by analysis of 3-min samples of expired air. As the H_2 concentration of expired air was often too low to measure accurately, a rebreathing technique, a modification of the method of Levitt (1969), was used to concentrate the breath H_2. An infant circle, which is normally used for anaesthesia of infants, was used as the collecting system. The apparatus contains a flutter valve, CO_2 absorbent, 3-litre neoprene bag, and a 2nd flutter valve. Hydrogen was considered to be evenly distributed in a volume of gas equal to that present in the collecting system, plus the residual lung volume of the subject (estimated from a nomogram for normal Japanese children (Nakajima, 1967)). The volume of the infant circle (except for bag volume) was measured by the dilution method and the average value in 20 determinations was 980 ± 20 ml. After the collection period, the bag volume was measured. The total volume was taken as 980 ml, plus the bag volume, plus the residual lung volume. This total volume multiplied by the concentration of H_2 in the collecting system was defined as the volume of H_2 excreted during a 3-min period. The system was flushed with O_2 between collections. With infants of <6 months old, expired air was collected by a modification of the to-and-fro rebreathing method of Krauss and Auld (1970). For this, a neoprene rubber bag of 1·5 litres was used, and the volume of the collecting system was nearly equal to the bag volume, because the dead space was very small (about 20 ml).

As soon as possible after collection, samples were analysed for H_2 by gas chromatography using a thermal conductivity detector (Shimazu Seisakusho, Ltd, Model GC-4B, Kyoto, Japan). A 2-ml sample of gas was introduced through a gas sample valve into a stainless steel column, 2 m × 0·4 cm (inside diameter), packed with 80-mesh molecular sieve 5A. Oven temperature was 75°C. N_2 (flow rate 20 ml/min) was used as carrier gas. The smallest detectable amount of H_2 was 5 ppm (0·05 ml in 10 litres), corresponding to the excretion of 0·0025 ml/min (as the minimum volume of the collecting system was about 1·5 litres). A single H_2 determination took only a few minutes.

Plasma glucose

Venous blood samples were obtained at 0, 30, 60, 90, and 120 min after glucose and lactose loading. Plasma glucose was determined by the glucose oxidase method.

Results

Out of faecal specimens from the 50 infants, 48 samples produced considerable hydrogen. The mean fasting breath H_2 output of 80 subjects was $0{\cdot}027 \pm 0{\cdot}016$ ml (1 SD)/min per m^2 (range 0·000 to 0·068). Usually the peak level for H_2 concentration occurred 2 or 3 hours after oral sugar administration. The fasting levels were subtracted from the peak levels, and the results were expressed as the increase above the fasting level. The reproducibility of the technique for collecting breath H_2 was studied in 4 infants and 4 children during a lactulose (unabsorbable sugar) loading test by comparing their rates of breath H_2 excretion during 2 consecutive 3-min periods ($n = 16$). The mean difference between the 2 determinations was 10·7% with a range of 1·3 to 15% (range of H_2 concentration was 27 to 167 ppm). The change in breath H_2 excretion in healthy subjects (7 infants, 7 preschool children, and 7 schoolchildren) after oral ingestion of lactulose or glucose (an absorbable sugar) is shown in Fig. 1. Breath H_2 excretion increased markedly (>0·05 ml/min per m^2) in each of the 21 subjects after ingestion of 0·5 g/kg lactulose (10% solution), but did not increase above the basal level after ingestion of 2 g/kg glucose. In fact, in the subjects given glucose, breath H_2 excretion decreased gradually.

In these 21 subjects, 2 congenital lactase-deficient

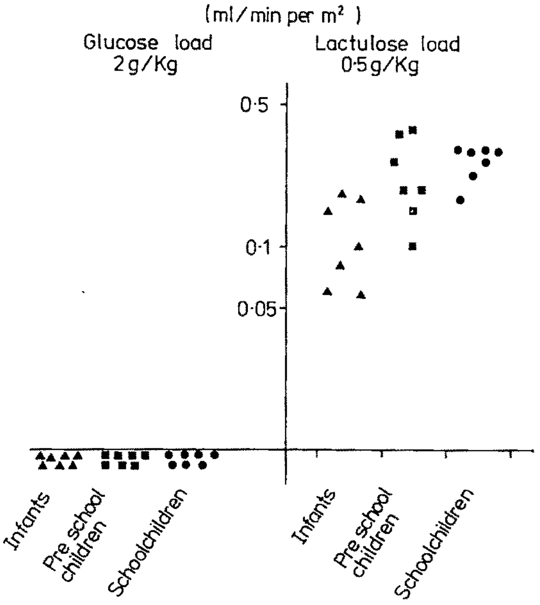

Fig. 1 *Maximum increase of breath H_2 excretion after oral administration of glucose (2 g/kg) and lactulose (0·5 g/kg), in children of various ages. Increase in H_2 is expressed as ml/min per m^2 body surface area.*

infants, and 7 normal adults, we compared the relationship between the maximum increase of breath hydrogen excretion and the maximum increase of the blood sugar level after oral ingestion of 2 g/kg (maximum 50 g) lactose (10% solution).

Fig. 2 shows the maximum increase in blood sugar in each subject plotted against the maximum increase in breath H_2 excretion. Subjects who had a normal tolerance test—that is, >20 mg/100 ml (1·1 mmol/l) increase in blood sugar—showed less than 0·05 ml/min per m² increase in H_2 excretion, and no clinical response. On the other hand, those who had <20 mg/100 ml increase in blood sugar showed an increase in breath H_2 excretion of >0·05 ml/min per m² and some of these subjects developed clinical symptoms—such as diarrhoea, cramp, bloating, flatulence, or borborygmi—particularly the 6 adults and 2 congenital lactase-deficient infants.

To examine the effect of age on H_2 excretion, we carried out the breath hydrogen test after oral ingestion of 1 g/kg lactose (10% solution) in 80 healthy infants and children and 18 adults. The maximum increase in breath H_2 is plotted against age in Fig. 3. All the infants and children of under 2 years could absorb lactose completely, but 30% of the 3-year-old children showed an increase of breath H_2 >0·05 ml/min per m², indicating lactose malabsorption. The incidence of lactose malabsorption was 36% in 4-year, 58% in 5-year, 86% in 6-year-old children, 85% in schoolchildren, and 89% in adults.

Discussion

A simple, reliable, and noninvasive test of sugar absorption is required for diagnosis and for studying malabsorption syndromes and adult-type lactose malabsorption in children. The technique of intermittent breath sampling for analysis of breath H_2 was developed by Levitt (1969) and is now established as the most accurate indirect test of disaccharide intolerance in adults. However, this test had not been applied to infants and children with a total collection method, so we adapted it for use on children.

We first tested whether the intestine of children contains the H_2-producing bacteria that are essential

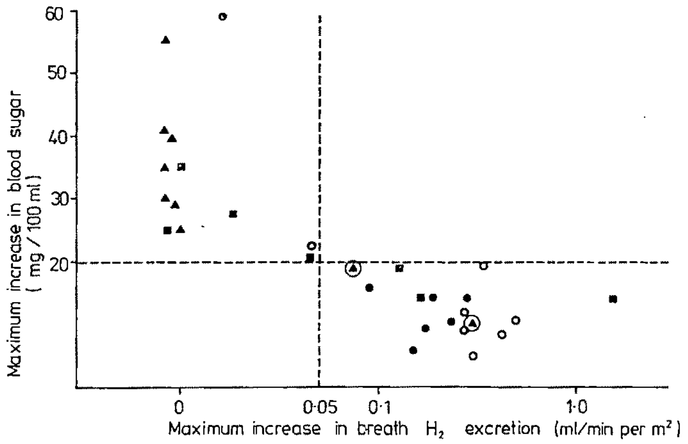

Fig. 2 *Relationship of maximum increase in breath H_2 excretion with maximum increase in blood sugar level after ingestion of 2 g/kg lactose (▲ infants, ■ preschool children, ● schoolchildren, Ⓐ congenital lactase-deficient infants, o adults).*

Conversion : traditional units to SI—blood glucose 1 mg/100 ml ≈ 0·0555 mmol/l.

for application of this test. *In vitro* tests on the faeces of 50 infants of various ages showed that almost all (96%) infants have colonic flora that produce H_2. Thus the breath H_2 test may be applied to infants. The breath H_2 collecting technique used by Newcomer *et al.* (1977) is an accurate method for older children, but the apparatus is too big and complex for children under 5 years and the rebreathing time too long, so that accuracy may be poor. The methods of end-expiratory breath H_2 sampling reported by Maffei *et al.* (1977) and Caskey *et al.* (1977) can give good information, but it is less precise than the total collection method (Metz *et al.*, 1976). However, as the total volume of collecting system is small in our method, and a detectable increase in concentration of H_2 gas in the system can be obtained in 3 minutes, we achieved satisfactorily accurate quantitative sampling of breath H_2. To reduce the total volume of the collecting system for infants under 6 months, the expiratory air was sampled using a to-and-fro rebreathing system. Our technique for collecting breath H_2 gave reproducible results, even with children under 5 years.

According to Newcomer and McGill (1977), 25 g (0·3–0·5 g/kg) of unabsorbed sugar may be enough to provide a distinct increase in breath H_2 in adults. On the other hand, we found that some patients began to develop clinical symptoms—such as diarrhoea, borborygmi, and abdominal distention—after administration of >0·5 g/kg lactulose, suggesting that the presence of more than 0·5 g/kg of unabsorbed sugar in the large intestine may cause clinical symptoms. So we tentatively made the presence of 0·5 g/kg unabsorbed sugar in the large intestine a diagnostic criterion of sugar malabsorption. For example, if an infant of 10 kg was given 10 g lactose, half of which was not absorbed (absorption rate 50%), a certain amount of H_2 would be produced. On the other hand, if a man of 50 kg was given 50 g lactose, and 5 g lactose was not absorbed (absorption rate 90%), H_2 excretion derived from unabsorbed sugar may be the same, since the amount of breath H_2 may reflect the absolute amount of unabsorbed sugar (Bond and Levitt, 1976). We thus thought it reasonable to establish a criterion of sugar malabsorption in BHT, by dividing H_2 excretion/min by body surface area. We first attempted to demonstrate an appreciable maximum increase in breath H_2 after oral administration of 0·5 g/kg lactulose to healthy infants and children of various ages. As shown in Fig. 1, even in infants, a definite increase of breath H_2 excretion (>0·05 ml/min per m²) was detected after administration of 0·5 g/kg of unabsorbable sugar (lactulose). On the other hand, when an absorbable sugar (glucose) was administered (2 g/kg) to the same subjects, no increase of breath H_2 was observed in any age group. These findings show that our method is reliable and accurate for evaluating sugar absorption. Moreover, as Fig. 2 shows, there was good correlation between the results of the ordinary lactose loading test and the results of the breath H_2 test.

We then carried out the breath H_2 test after oral ingestion of 1 g/kg lactose to determine the incidence of lactose malabsorption. We chose this dose of lactose for the following reasons: (1) it is more physiological than that ordinarily used (2 g/kg), because uptake of lactose, at one time, from the diet does not usually exceed 1 g/kg (Hegsted, 1976; Newcomer *et al.*, 1978); (2) the absorption of less than half the administered lactose may be reasonably defined as lactose malabsorption. Thus, judging from the fermentation of various sugars (Bond and Levitt, 1972) and our results with lactulose loading, if half the lactose is not absorbed after a load of 1 g/kg, there should be an increase of breath hydrogen $>0 \cdot 05$ ml/min per m^2.

Our results showed that all infants and children under 2 years could absorb lactose completely. Lactase deficiency seems to appear at 3 years and it gradually increases with age; 85% of the children of over 6 years, and about the same percentage of adults, showed lactose malabsorption.

There have only been two previous reports on the age of onset and prevalence of lactose intolerance in Japanese people. Shibuya *et al.* (1970) reported a somewhat earlier age of onset of lactose intolerance and 100% incidence of lactose intolerance after 8 years by using the ordinary lactose tolerance test. As the ordinary lactose tolerance test gives about 20% false-positive results (Krasilnikoff *et al.*, 1975), their results are not essentially different from ours. Naito *et al.* (1973) investigated the effect of age on lactase activity, and found an adult-type pattern of lactase activity in children of over 6 years.

There are two reports of studies on American Indians using breath H_2 analysis. Newcomer *et al.* (1977) observed lactase deficiency by age 5, but they did not obtain satisfactory results on younger children; Caskey *et al.* (1977) made similar studies but their results are not comparable with ours because of the difference in method.

The breath H_2 test has many advantages (Metz *et al.*, 1976; Fernandes *et al.*, 1978) and should have wide application for elucidating problems of sugar absorption in children.

We thank Mrs Ichihara and Mrs Nose for their help in preparing the manuscript. This investigation was supported in part by grant from the Ministry of Education in Japan.

Giant exomphalos—conservative or operative treatment?

DAVID C. S. GOUGH AND ALEX W. AULDIST

Royal Children's Hospital, Parkville, Victoria, Australia

SUMMARY The rate of survival for infants with intact giant exomphalos has much improved during the last 20 years; this is partly due to better respiratory and nutritional support. The use of a staged operative closure using a sialon prosthesis has been advocated for 12 years, but our data do not show this to be superior to nonoperative management.

Children with intact exomphalos pose considerable problems in management. The first question is whether an operative or a nonoperative method should be used when simple closure is not possible either because of the size of the defect or because of the contents of the sac.

Nonoperative treatment using drying agents—such as mercurochrome or alcohol—to encourage cicatrisation, first advocated in 1899 by Ahlfeld, still has support, and if it is successfully used the child is left with a soundly healed abdominal wall or one that requires little subsequent surgery (Grob, 1963; Soave, 1963).

The skin mobilisation method of surgical treatment (Olshaussen, 1887; Gross, 1948) usually leaves an enormous hernia and there are significant technical problems in later repair of the abdominal wall. Subsequent surgery for this defect carries a mortality rate of 27% (Shuster, 1967).

Survival rates of patients with large exomphalos have been poor; in Melbourne between 1952 and 1962 the mortality rate was 75% for infants with defects of 5 cm or more across (Jones, 1963).

The arrival of a new concept in treatment, that of staged reduction by exterior pressure applied with a sac sutured to the edge of the defect (Shuster, 1967) was greeted by many surgeons as the answer to this problem. The aim of this treatment was to reduce the defect as quickly as possible with early discharge of the patient from hospital. However, our experience with this method of treatment has not been entirely satisfactory, so we were prompted to review our patients.

Materials and methods

Between 1967 and 1977, 87 patients were admitted to the neonatal unit of this hospital with intact exomphalos. 17 of these had defects measuring >5 cm diameter at the base, and they were retrospectively reviewed. Primary closure of muscle and skin was possible in 3 of them, 6 were selected according to the preference of the responsible surgeon for treatment by the Shuster technique using a sialon pouch, and 8 were similarly chosen for nonoperative treatment.

Results

There were 3 patients in whom primary closure was possible with a survival rate of 100%. One child has had two exchange transfusions for jaundice and at review had a pronounced hearing loss. There were no other medical or surgical problems in this group and their stay in hospital was about 3 weeks.

Two of the 6 patients treated with sialon prosthesis died. None had any other major malformation and both deaths were in the first 2 weeks of life. The cause of death was Gram-negative sepsis while on appropriate chemotherapy. Two of the survivors needed major reconstructive surgery of the abdominal wall and this was completed successfully. The patients treated by this staged repair stayed in hospital for between 4 and 7 weeks, but we noted that during the period that the prosthesis was *in situ*, no patient could be successfully established on alimentary feeding, so total parenteral nutrition was undertaken routinely in this group.

Eight patients were given conservative treatment and 3 of them died. Two deaths were due to associated malformations; one death at 24 hours was due

Royal Children's Hospital, Melbourne
ALEX W. AULDIST, consultant paediatric surgeon

to Potter's syndrome and the other, from cardiac failure at age one week, was due to Fallot's tetralogy. Both diagnoses were confirmed at necropsy. In the remaining 6 patients the intact sac was painted with 2% aqueous mercurochrome. There was one death of a child in this group caused by achromobacter sepsis while he was being given inappropriate treatment with antibiotics, and 4 of the survivors have had, or will need, minor reparatory surgery to their umbilical defects. One child in this group was diagnosed as having mercury intoxication due to mercurochrome applications. He had a 9 cm defect (Fig. 1) and after initial sepsis and respiratory failure requiring ventilation failed to thrive at age 8 weeks (Fig. 2). Mercurochrome 2% had been applied daily to wet areas. At this stage we proceeded with pure alcohol solutions as the only application and he then showed satisfactory weight gain (Fig. 3). One other patient in the series is mentally retarded with microcephaly. We believe this may be a case of undiagnosed mercury intoxication. Patients treated conservatively stayed in hospital for a time varying between 6 and 16 weeks.

Discussion

The object of treatment of these children should be primarily to save life, but an important consideration is to achieve a sound abdominal wall with as short a stay in hospital as possible. In this hospital there has

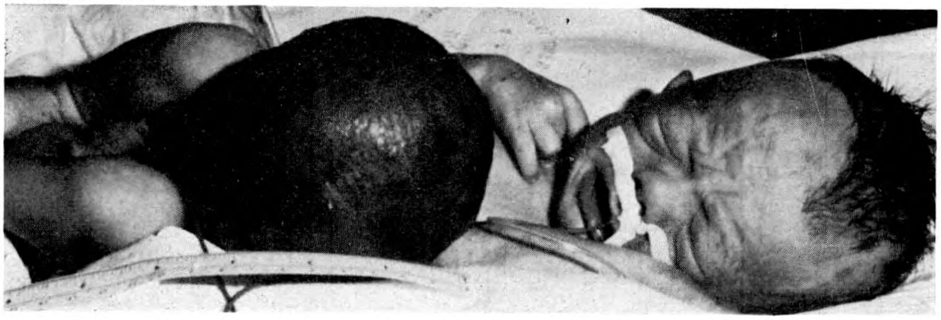

Fig. 1 *Case 1. Mercurochrome treatment aged one day.*

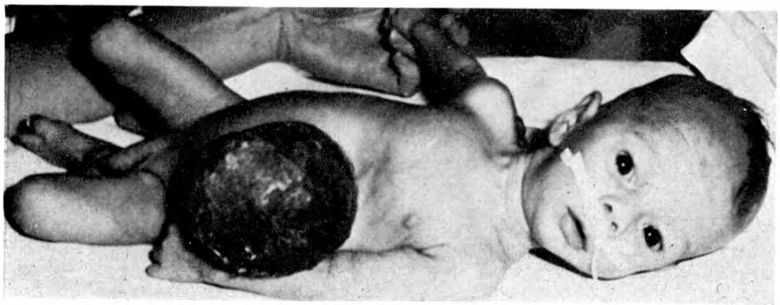

Fig. 2 *Case 1. Mercurochrome treatment aged 8 weeks.*

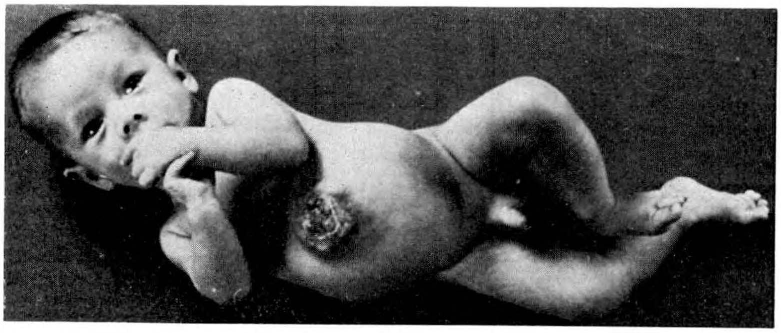

Fig. 3 *Case 1. Mercurochrome treatment aged 11 months.*

been an overall improvement in results: in 1952–62 there were 3 survivors out of 13 patients (Jones, 1963), in 1967–77 there were 12 survivors out of 17 patients. Improvements in the supportive care, particularly better respiratory support and nutritional techniques, seem primarily responsible for the higher rates of survival.

Several reports have confirmed the safety of non-operative treatment (Grob, 1957, 1963; Soave, 1963; Firor, 1971; Ryan, 1973). Even among the writings of surgeons who favour an aggressive surgical approach there are reports which show 28 survivors from 34 patients treated conservatively (Kim, 1976) These figures are mirrored closely by current results.

We are not aware of any substantial series of patients treated by the Shuster method that has better results. In fact Shuster's original series of 11 neonates with intact exomphalos treated by his own method, remains the largest single series and is still the most successful, with 9 patients surviving.

More recent and smaller series have shown mortality rates to be between 33 and 50% (Gilbert *et al.*, 1968; Ryan, 1973). A combination of staged reduction with skin or sialon prosthesis achieved good results in all 4 patients operated on by Mahour *et al.* (1973). Some arguments support operative management and emphasise that other anomalies may be present—such as gut atresia or diaphragmatic hernia (Mahour *et al.*, 1973). In our experience these anomalies can be diagnosed by clinical and radiological examination and, if present, may dictate a purely surgical approach, although their surgical correction may not of course prevent mortality.

The long-term aim of a soundly healed abdominal wall can be achieved in most patients by either technique. Secondary surgery will be necessary in many patients, as shown in this series and confirmed by others (Shuster, 1967; Gilbert *et al.*, 1968), but the extent of operation is usually less in those who have been treated conservatively initially.

Sepsis is now the overriding problem in all methods of treatment. These patients stay a long time in intensive care units, and the use of systemic antibiotics and local antiseptics does not always prevent severe and sometimes life-threatening infections. This complication was responsible for the 3 preventable deaths in our series. Our experience has been that appropriate treatment with antibiotics controls sepsis more effectively in the absence of a foreign body prosthesis.

The risk of mercury poisoning with the use of mercurochrome has been emphasised (Fagan *et al.*, 1977). We believe this can be overcome by using mercurochrome without the impurity of free mercury and by using it only for a short period. We have also experimented with the use of a drying agent—such as alcohol not containing mercurochrome.

Other complications of conservative treatment—such as volvulus (Grob, 1963)—have been seen with the use of sialon prosthesis, but we did not encounter them. Since completing this series we have had one patient in whom the exomphalos sac ruptured while undergoing conservative treatment; this was successfully treated with a sialon prosthesis.

As long periods of stay in hospital are necessary in all forms of treatment, we encourage the parents to participate in the treatment of the child (Fig. 4).

Conclusions

At the Royal Children's Hospital, Melbourne, the survival of infants with intact giant exomphalos has improved significantly since the reported

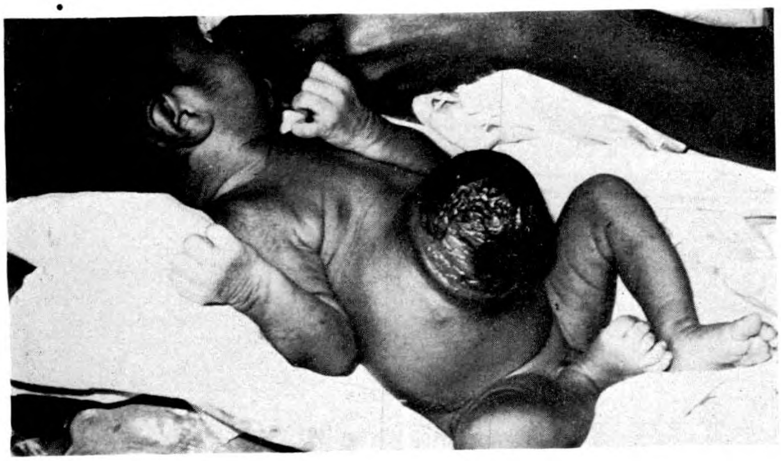

Fig. 4 *Case 2. Mercurochrome treatment aged 2 weeks, breast feeding.*

mortality for the period 1952–62 of 75%, to 12 survivors in 17 patients in the current series. Improved respiratory support, intravenous nutrition, and new antibiotics have all contributed.

The results now reported indicate that if primary operative closure is not possible there is little difference in mortality between nonoperative management and staged operative closure using a sialon prosthesis.

We thank the staff of the Royal Children's Hospital for permission to publish these results.

Defective Candida killing in childhood malnutrition

ROGER TUCK, VALERIE BURKE, MICHAEL GRACEY, ANNE MALAJCZUK, AND SUNOTO

The Regional Hospital, Derby and Princess Margaret Children's Medical Research Foundation, Perth, Western Australia, and the Department of Child Health, University of Indonesia, Jakarta

SUMMARY This study shows that malnourished children have impaired candidacidal activity of leucocytes, a finding which runs parallel to the higher rates of isolation of *Candida* sp. from throat secretions. In well nourished subjects the mean candidacidal ability was 44·5%, in the moderately undernourished group it was 17·6%, and in the severely malnourished group it was 13·7%. This impaired candidacidal capacity may be important in the establishment of large numbers of *Candida* sp. which are commonly found in the upper intestine and in the pathogenesis of diarrhoea in children with malnutrition.

Candida species are common in the upper intestinal contents of malnourished children (Mata *et al.*, 1972; Gracey *et al.*, 1974) and may contribute to the production of diarrhoea by their effects on intestinal absorption of sugar (Burke *et al.*, 1977) and water (Thelen *et al.*, 1978). The mechanism by which such large numbers of *Candida* become established in malnourished children is not clear. Previous studies have shown the ability of such children to secrete intestinal immunoglobulins to be unimpaired (Bell *et al.*, 1976), while depression of cell-mediated immunity *in vivo* and *in vitro* has been reported in malnutrition (Geefhuysen *et al.*, 1971; Chandra, 1972; Ferguson *et al.*, 1974). However Kulapongs *et al.* (1974) found lymphocyte responsiveness to phytohaemagglutinin and killing ability of polymorphs to be normal in a group of malnourished children with iron deficiency, while Macdougall *et al.* (1975) found cell-mediated immunity was impaired in such children. Bactericidal function of polymorphs was assessed using *Escherichia coli* as the test organism in the study of Kulapongs *et al.* (1974), but Macdougall *et al.* (1975) and other investigators, showing impaired killing ability of polymorphs (Seth and Chandra, 1972), used staphylococci. It may be that bactericidal function is reduced only in relation to specific organisms.

Lehrer and Cline (1969) showed that leucocytic function was important in resistance to Candida infection. Using their technique, it was shown that the Candida-killing ability of polymorphs is reduced in newborn babies, a group known to be susceptible to mucosal candidal infections (Xanthou *et al.*, 1975). Because of our interest in gastrointestinal candidiasis in malnourished children we investigated the Candida-killing ability of polymorphs in such children.

Materials and methods

Patients. Blood and throat swabs were obtained from 67 children and adults. Patients were classified according to the recommendations of the Wellcome Working Party (*Lancet*, 1970) into a normal group with body weights >80% standard weight for age (SWFA), an underweight group 60–80% SWFA, and a marasmic group <60% SWFA. Samples of 4 ml heparinised blood were obtained by venepuncture from normal adults, well nourished children without known immunological deficiencies attending Princess Margaret Hospital in Perth, Indonesian children admitted to hospital in Jakarta, and from Australian aboriginal children in hospital in Derby, an isolated country town on the coast in the far north of Western Australia.

Candida-killing ability of leucocytes. The method of Lehrer and Cline (1969) was used with the modifications of Xanthou *et al.* (1975) to minimise the volume of blood taken from the children. Killing

ability was measured by counting the number of Candida stained by methylene blue which distinguishes killed organisms, after incubating comparable numbers of neutrophils and viable Candida in serum with Hanks's solution for 30 minutes at 37°C. All tests were done using patients' sera as well as with normal adult sera. At least 300 cells were counted for each sample and results are expressed as the number killed—that is, blue-stained Candida/100 phagocytosed organisms. Differences in percentage of Candida killed in groups classified according to nutritional status were assessed using the Kolmogorov-Smirnov test.

Throat swabs. Specimens were collected into Stuart's transport medium and refrigerated at 4°C if not processed immediately. Those from Derby and Jakarta were flown to Perth on ice and processed within 24 hours of collection. Throat swabs were cultured in Sabouraud's dextrose agar and incubated for 48 hours at 25°C.

Results

Candida-killing ability was not related to age, race, or diagnosis on admission to hospital. Consequently, results were considered only in relation to the patient's nutritional state.

In the well nourished group the mean candidacidal ability was 44·5% (SEM 8·8), for those with weights 60–80% SWFA the mean was 17·6% (SEM 4·4), and for children with weights <60% of SWFA the mean was 13·7% (SEM 3·4). Results are shown in the Figure. Comparison of each malnourished group with the well nourished subjects showed the difference to be highly significant (P<0·001). However, there was no significant difference in candidacidal ability between the two groups of malnourished children. Addition of normal sera in place of the patients' own sera did not alter the Candida-killing ability of their leucocytes.

We previously showed (Gracey *et al.*, 1973) that oropharyngeal flora probably reflect environmental contamination, so that it is invalid to compare isolation rates of organisms from such different areas as Perth, Derby, and Jakarta. As there were no malnourished children from Perth, results of throat swabs taken in Perth were not included in the analysis. Children from Derby and Jakarta were grouped according to nutritional status and separate comparisons made for each area. In Jakarta, 92% of malnourished children had *Candida* in their throat swabs compared with 66% of normal children; in Derby *Candida* was grown from throat swabs of 80% of malnourished children but from only 14% of normal children.

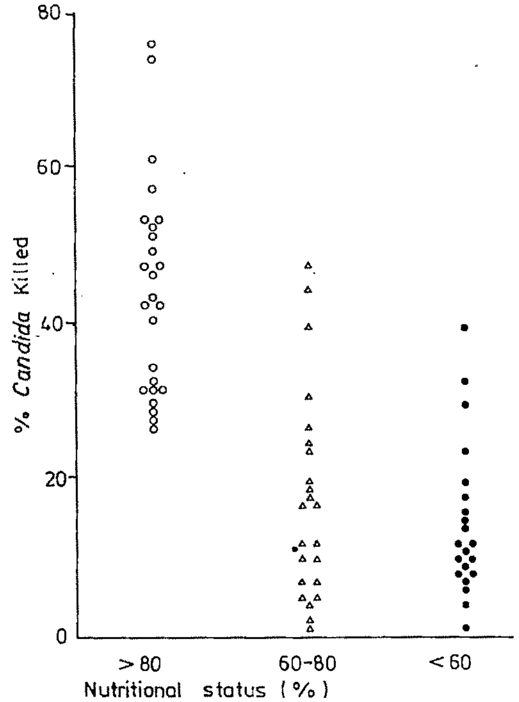

Figure *Candida-killing capacity (expressed as percentage of Candida killed) according to nutritional status expressed as a percentage of standard weight for age compared with the 50th centile of the Harvard standards (Lancet, 1970).*

Discussion

We show that malnourished children have reduced candidacidal activity of their leucocytes. This finding runs parallel to the higher isolation rate of *Candida* sp. from throat swabs of malnourished children. The defective Candida-killing ability of these leucocytes was not corrected by adding normal serum. Lehrer and Cline (1969) found that serum factors did not affect the candidacidal property of leucocytes and the addition of normal serum did not correct defective Candida-killing by leucocytes in the newborn (Xanthou *et al.*, 1975). It would seem that malnourished children also have impaired leucocyte function in relation to *Candida* killing. We found that the Candida-killing ability of leucocytes was reduced in patients with a high isolation rate of *Candida* sp. from their throat swabs. Organisms isolated from the upper small bowel are similar to the flora of the oral cavity (Dickman *et al.*, 1976) and our previous investigations suggest that *Candida* sp.

are likely to be found in the upper intestinal contents of these children (Gracey *et al.*, 1974). The relationship between gastrointestinal infection with *Candida* sp. and impaired *Candida*-killing ability of leucocytes is not clear. Although several investigators have established the importance of intestinal antibodies in controlling bacterial contamination of the upper intestinal contents (Walker and Isselbacher, 1977), their role in relation to intestinal candidiasis is not known. However, malnutrition does not impair secretion of immunoglobulins into the intestinal lumen as intestinal immunoglobulin levels have been shown to be raised in malnourished children with infections (Bell *et al.*, 1976). The importance of leucocytic function in maintaining the relative sterility of upper intestinal contents has not been widely investigated. However Takeuchi *et al.* (1965) and Kenworthy (1970) showed that phagocytosis was important during the establishment of experimental infections with *Shigella* and *E. coli.* It may be that neutrophils are also important in controlling candidal infections in the small intestine.

Our findings show that polymorphs from malnourished children have an impaired ability to kill Candida and extend the observation that the ability to kill *Staphylococcus pyogenes* is reduced in malnutrition (Seth and Chandra, 1972). This mechanism may contribute to the significantly increased incidence of candidal infections in malnourished children.

We thank everyone in Australia and Indonesia who took part in this study, and the doctors and nurses who helped to collect and transport the specimens.

R.T. was seconded from the Princess Margaret Hospital for Children, Perth, Western Australia.

Bronchial asthma in Nigerian children

W. I. ADERELE

Department of Paediatrics, University College Hospital, Ibadan

SUMMARY Clinical and laboratory studies on bronchial asthma in 200 Nigerian children who were seen during a 2½-year period in Ibadan are described. Contrary to reports that the condition is rare in African children, after pulmonary tuberculosis, asthma is the next most common chronic chest disease in Ibadan. While many features of the disease are similar to those seen elsewhere, skin tests indicate that ascaris is the most common antigen associated with asthma, followed by *Dermatophagoides pteronyssinus*.

Bronchial asthma, a common childhood chronic respiratory problem in the West (Godfrey, 1974), is reported to be rare among African children (Wesley *et al.*, 1969; Godfrey, 1975; Warrell *et al.*, 1975).

While studies by Mitchell (1970), Sofowora (1970), Anim and Edoo (1972), and Buchanan and Jones (1972) showed that the condition is common in African adults, Wesley *et al.* (1969) reported that bronchial asthma is extremely rare among Bantu children in South Africa. In Nigeria, Warrell *et al.* (1975) reported that asthma is rarely seen in children living in the savanna region of the country. Our experience at this hospital in Ibadan during the last few years indicates that the condition is far more common in children here than these reports suggest. This paper gives the results of studies on 200 asthmatic children seen at this hospital during a 2½-year period (June 1974 to December 1976).

Materials and methods

The patients in this study were referred to the chest clinic mainly from the general outpatient department of the hospital but some came from private clinics and hospitals in Ibadan and nearby. Diagnosis of asthma was based on a history of at least three attacks of breathlessness and wheezing (Blair, 1969), often associated with cough, and usually supported at the time of initial examination or during subsequent follow-up, by the auscultatory finding of widespread respiratory rhonchi. In some patients who presented in acute attacks, the diagnosis was further supported by the demonstration of at least 20% increase in the peak flow (measured with a Wright's peak flow meter) after the administration of a bronchodilator.

Laboratory investigations carried out on the patients included packed cell volume, white blood count—total and differential—stool microscopical examination, chest *x*-rays, and in a few children, the radiology of the paranasal sinuses. Skin sensitivity tests were done by the prick method, using a selected range of commercially prepared allergen extracts (Bencard). The weal diameter of the reaction recorded was the difference in mm between it and the control. Weals of at least 2 mm in diameter were regarded as positive (Pearson, 1973).

The children were classified into three groups according to the severity of the disease. This grading system was modified from one described by Dawson *et al.* (1969). The *severe* group consisted of patients with more than 10 acute attacks a year with or without complete clinical recovery between attacks. The *moderate* group had 5 to 10 attacks a year and usually showed complete or partial freedom from wheezing between attacks, while the *mild* group had 1 to 5 attacks a year with complete clinical recovery between attacks.

Results

Age at presentation and sex incidence. The children were aged between 10 months and 13 years; 97 (49%) of them were less than 5 years. The boy/girl ratio was 1·6:1.

Age of onset. As shown in the Figure, 125 (63%) children had their first attacks before age 3 years.

Referral diagnoses. Diagnosis of asthma or asthmatic bronchitis was made before referral in 136 (68%)

Department of Paediatrics, University College Hospital, Ibadan, Nigeria
W. I. ADERELE, senior lecturer

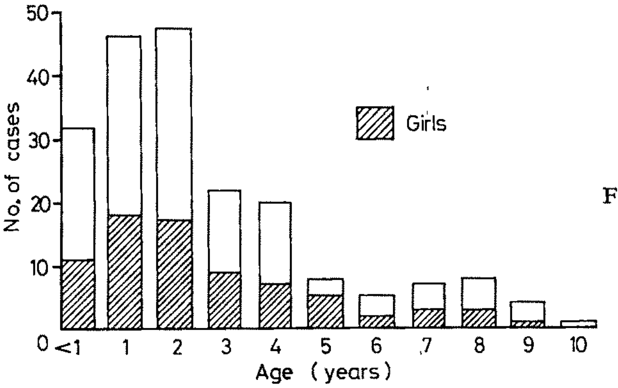

Figure *Age of onset in 200 children with asthma.*

cases, while 18 (9%) were referred as cases of pulmonary tuberculosis, 15 as cases of bronchopneumonia, and 5 (3%) were thought to be cases of acute bronchitis or bronchiolitis. Other referral diagnoses included chronic bronchitis, chronic chest infection, and lobar pneumonia. In 15 cases, no diagnosis had been entertained at the time of referral.

Early feeding. 166 (98%) of 170 children whose early feeding histories were reliably ascertained were breast fed from birth. This is similar to the rate of 99% in 385 Ibadan women from all social classes who breast fed (Omololu, 1972). 145 (85%) of the same 170 children were fed on artificial milk, generally in addition to the breast milk; in 55% of them this was from the first week of birth. This proportion of those fed on artificial milk contrasts with 78% (range 45% in illiterate women to 99% in 'élites') of the women in Omololu's series who fed their children partially or wholly on artificial milk.

Family and social histories. Table 1 shows that there were 127 (63·5%) patients who came from the upper socioeconomic classes (classes I, II, and III). This compares with an estimated 20% of these three classes attending hospital for other respiratory complaints. There was a positive family history of allergy in 79 (40%) of the 200 patients. 73 of these were siblings or parents suffering from asthma, but 5 parents had allergic rhinitis, and one sibling suffered from eczema. 78 (39%) of the 200 children were attending school, and of these, 14 were often absent from school because of asthmatic attacks. 74 (38·9%) of 190 families had domestic animals or pets—such as chickens, dogs, cats, or goats.

Precipitating and associated factors. There was a positive history of precipitating factors in 155 (78%) of cases (Table 2), leaving 45 cases where there was none.

Presenting symptoms. The predominant symptom was breathlessness during attacks noted in all 200 children. Cough and wheezing were the next most common, both occurring in 96% of children. Other common and frequent symptoms included sweating (most profuse on the forehead during acute attacks), anorexia and loss of weight, which occurred while the attack lasted and abated soon after it ceased. Symptoms of chest pains and headaches were given by patients older than 5 years. Sputum, mixed with

Dry season	7	3·5
Dust	5	2·5

streaks of blood (often slight and infrequent), was present in 8 (4%) patients.

Physical signs

Physical growth

Weight and height were recorded in 169 patients at the first visit to the clinic, and weight alone was recorded in 28 others. The figures were plotted on centile charts for British children (Tanner *et al.*, 1966). According to Janes (1970), the weights and heights of élite or privileged Nigerian children of both sexes compare favourably with those of British children, hence the use of British centile charts. 63 (32%) of the 197 children had weights <10th centile, while 151 (77%) were <50th centile. The corresponding figures for heights were 40 (24%) of 169 <10th centile and 109 (65%) <50th centile.

Respiratory signs

No abnormal auscultatory signs were present in 102 (51%) of the 200 cases at the initial visit. There was audible wheeze in 30 of the remaining 98 patients, and the other children had abnormal signs only on auscultation. These abnormal auscultatory signs consisted of inspiratory and expiratory rhonchi in 59 children, expiratory rhonchi alone in 23, inspiratory rhonchi alone in 8, and combined rhonchi and crepitations in the remaining 8 patients. There was a barrel-shape chest deformity in 19 (10%) of the 200 patients.

Other signs

10 children (5%) had flexural eczema which had been present from infancy in 2 of them and was quiescent in 7 others; vernal conjunctivitis was present in 19 (9·5%) patients.

Severity of asthma

58 (29%) of the 200 patients were classified as having severe asthma, while 30 (15%) had a moderate type, and in 112 (56%) of them it was mild.

Investigations

Skin sensitivity tests. Skin tests were performed on 139 children using between 10 and 30 allergen extracts. The results were negative in 46 (33%) of the children. Table 3 shows the 10 most common allergens to which the remaining 93 patients were sensitive. Ascaris antigen topped the list of positives, followed by *Dermatophagoides pteronyssinus* and house dust.

Table 3 *Skin reactions to individual allergens**

Allergen	*No. tested*	*% positive*
Ascaris	77	34
D. pteronyssinus	139	22
House dust	115	18
Flower and shrub pollens	77	18
Cat fur	115	16
Grass pollen	139	14
Feathers	115	12
Fish	77	11
Meat	77	11
Cockroach	77	9

*Other allergens tested were cows' milk, whole egg, tree pollen, mixed yeast, *Aspergillus fumigatus*, dog hair, goat hair, fruits, plantain, horse hair, moulds (A13, M5, M10, M11), cereals, cotton flock, mosquito, sheep wool, human hair, and chocolate.

Table 4 *Chext x-ray findings at presentation in 190 asthmatic children*

Finding	*No. of cases*	*% of cases*
Normal	59	31
Increased linear lung markings alone	40	21
Increased linear lung markings and increased hilar shadows	21	11
Inflammatory changes/bronchopneumonia	39	21
Peribronchial thickening	24	13
Hyperinflation	4	2
Lobar consolidation	2	1
Calcification and inflammatory changes	1	0·5

Chest x-rays. The findings in 190 cases are shown in Table 4. 99 (52%) of the 190 had normal films or a slight linear increase in lung markings. Only 4 (2%) showed evidence of hyperinflation (most of the films were not taken during acute attacks). It is noteworthy that 11% of the patients had increased lung markings and increased hilar shadows mimicking hilar lymphadenopathy.

Paranasal sinus x-rays. These were done in 32 patients, 22 (69%) of whom had normal sinuses while 8 (25%) showed thickening of the mucosa; clouding of the sinuses was evident in only 2 children.

Blood eosinophilia and stool parasites. The mean eosinophil count in 168 children was 1166/mm^3 (1·1 × 10^9/l) (range 0–5562/mm^3; 0–5·5 × 10^9/l), compared with a mean count of 449/mm^3 (0·4 × 10^9/l) (range 0–1425; 0–1·4 × 10^9/l) in a group of 50 control children. In all, 67 (40%) of the 168 had eosinophil counts >1000/mm^3 (1·0 × 10^9/l). In relation to the total white blood count, the mean percentage was 13% (range 0–42%), compared with a mean of 5% (0–23%) for the controls. 87 (52%) of the 168 had percentages >11%.

Stool specimens from the children were examined at the same time that the eosinophil counts were done. Helminths, mainly the ova of ascaris and trichuris, were present in the stools of 120 of these patients. The eosinophil count (mean 1362/mm^3;

$1 \cdot 3 \times 10^9/l$) in asthmatic children with stool parasites was higher than the counts in those without parasites (mean 787/mm^3; $0 \cdot 7 \times 10^9/l$). However, in a group of 35 controls with stool parasites, the eosinophil count (mean, 510/mm^3; $0 \cdot 5 \times 10^9/l$) was lower still, suggesting that both the atopic state and helminthiasis contributed to the high eosinophil count in the patients with asthma.

Tuberculin skin test. These were carried out in 183 of the children. 102 (57 %) of these had negative tuberculin reactions while 75 (41 %) and 6 (3 %) had grades 1 and 2 respectively. In none of the children was there any other evidence of tuberculosis.

Haemoglobin electrophoresis. 179 children had genotype determinations. Of these, 140 had the normal A genotype while 39 (22 %) had abnormal genotypes (AS, 31; AC, 6; SC, 1; SS, 1). This proportion of abnormal Hb electrophoretic pattern is similar to that in the general population.

Discussion

Most of the features of asthma in the present series are similar to those described in children elsewhere. The male preponderance is in keeping with the findings of Dawson *et al.* (1969), and Davis (1976). 63 % of our patients had their first attacks of wheezing before age 3 years, similar to the findings of Wesley *et al.* (1969), but higher than the 44 % reported by Dawson *et al.* (1969) and the 32 % reported by Williams and McNicol (1969). Other similarities with the situation in the UK or Australia are found in the proportion of patients with a family history of allergy and in the common precipitating factors. Contrasting with these similarities, there are certain dissimilarities, notably the finding that the ascaris antigen was the most common allergen to which the skins of the children were sensitive. This sensitivity bore no consistent relationship with the presence of ascaris ova in the stool. Although the full significance of this finding is not clear, none of the 35 controls who has so far undergone skin tests with the ascaris antigen has had a positive reaction. Another dissimilarity is the proportion of children showing negative skin reactions to a battery of between 10 and 30 antigens. In the present series, 33 % of the children tested did not react to any antigen, including *D. pteronyssinus* and grass pollen. This is in contrast to the 20 % for asthmatic children in Melbourne (Williams and McNicol, 1969) and the 7 % quoted by Godfrey (1974) in the UK.

The incidence of asthma in European children has been estimated as 0·4 % in Helsinki (Eriksson-Lihr, 1955), 4·8 % in Aberdeen (Dawson *et al.*, 1969), and 9·9 % in Birmingham (Morrison Smith *et al.*, 1971). In Africa, a school survey in Nigeria showed a rate of 2·4 % (Sofowora and Clarke, 1969), and Carswell *et al.* (1977) reported a rate of 7·8 % in a group of Tanzanian children. These estimates, and those of the present series, suggest that bronchial asthma is as common a condition in Ibadan children as it is in European or Australian children. Yet elsewhere in Africa the condition is reported to be rare. In Kenya, the youngest patient reported by Wasunna (1968) in a series of 210 cases was 12. Mitchell (1970) also from Kenya reported that no child under 12 was seen from over 1200 asthmatic patients who attended the Kenyatta National Hospital, Nairobi, and Rees *et al.* (1974), reporting on 124 asthmatic cases from the same hospital, recorded only 18 patients under 21 years. In South Africa, Wesley *et al.* (1969), comparing the incidence of asthma in Durban children of three racial groups, concluded that bronchial asthma was extremely rare among Bantus. Warrell *et al.* (1975) reported that only one child was admitted with severe asthma during a period of 4 years in Zaria, Northern Nigeria, an area where the paediatric outpatient attenders number approximately 96 000 children each year. It thus appears that while the prevalence of asthma among adults is similar in many parts of Africa, there are wide variations in its prevalence in childhood. This variation may be attributed to the fact that the children in different areas of Africa are not exposed to adverse environmental precipitating factors—such as artificial feeding, atmospheric pollution, and other allergens—in the same way and at the same ages. Another possible explanation may be the difficulty in differentiating bronchial asthma from other forms of chronic respiratory disorders affecting children in Africa.

The fact that the diagnosis of bronchial asthma in environments such as ours depends mainly on its clinical features (provocation tests cannot easily be carried out), makes it inevitable that mistakes in diagnosis are common. Bronchial asthma can easily be confused with pulmonary tuberculosis, a common condition in African children, with the cardinal symptoms of cough, fever, anorexia, loss of weight, and night sweats, which also occur with bronchial asthma. (Even haemoptysis was present in 4 % of the cases in this series of asthma.) 9 % in the present series of asthmatic children were diagnosed as pulmonary tuberculosis before referral, and 2 of these were treated with antituberculous drugs for a prolonged period before the correct diagnosis was made. To avoid misdiagnosis, as great an emphasis should be placed on the history of recurrent attacks of breathlessness as on wheezing, for it is much easier to obtain a history of breathlessness than of wheezing in Africa where there are often no vernacular equivalents of the word, and where to elicit such symptoms the examiner must be able to mimic the wheezing sound.

I am grateful to Professor A. U. Antia for his advice on the preparation of this article, to the medical and nursing staff of the Paediatric Department, UCH, Ibadan for helping with the investigations, and Mrs T. Onireti for secretarial assistance.

Received 5 September 1978

Dr R. H. Dobbs, formerly Professor of Paediatrics in Zaria, Northern Nigeria, was invited to comment on this article.

This paper illustrates the difficulties in assessing the many environmental factors—social, ethnic, and climatic—that interact to bring out clinical manifestations in atopic children.

Climate is undoubtedly crucial and it is made clear, both in the text and in Table 2 of this paper, that in Ibadan, less than 100 miles from the south coast, the rainy season is an important precipitating factor of asthmatic attacks, whereas in Zaria, 100 miles from the northern frontier, where the dry season often extends throughout 9 or 10 months of the year, childhood asthma scarcely exists, and those few cases that are encountered there, are in the neighbouring densely urban town of Kaduna, and confined to the few rainy months.

Social class appears also to have much bearing on the incidence of childhood asthma and its delayed appearance until early adolescence. As recorded, in Ibadan 64% of patients were drawn from the relatively wealthy classes I to III, in contrast to only 20% attending with other respiratory illnesses. The almost universal reliance on breast feeding, and the late onset of cows' milk supplements in the poor may be an important factor in this delay, although the data are not sufficiently clear to draw conclusions.

It may be added that it is now thought that the protective factors in breast milk are more important than any immunologically deleterious action of cows' milk. But perhaps of even greater importance is the enormously high infant mortality rate, which may well lead to the elimination of a large proportion of the undernourished, immunologically deficient, and atopic infant population of the poorer classes, with the rich paying for their Darwinian survival with the development of childhood allergy.

The high frequency of positive skin tests to ascaris is of great interest, being in confirmity with previous studies. This does not necessarily mean that ascaris antigen is responsible for triggering the asthmatic state. Indeed it has been suggested that, on the contrary, because of high levels of IgE antibody to ascaris, most cell-binding sites may be blocked for antibody to other antigens, and thereby protect against asthma. This concept might seem to be countered by the author's statement that ' None of the 35 controls . . . has shown positive reactions (to ascaris)', an observation that is hard to understand in view of the worm infestation of African children in general.

A final point relating to the incidence of asthma in developing countries, although not discussed in this paper, is worth consideration—the rarity of asthma in young children of some localities and social classes is in contrast with its development as adolescence approaches. This is illustrated by the need to set up asthma clinics in Northern Nigeria; these are found to deal almost entirely with adult asthmatics. It seems that environmental factors can, with the passage of time, induce atopic disorders.

Carbamazepine dose-frequency requirement in children

G. W. RYLANCE, T. A. MORELAND, AND G. M. BUTCHER

Departments of Child Health, Pharmacology and Therapeutics, Ninewells Hospital and Medical School, and of Pharmacology and Therapeutics, University of Dundee

SUMMARY The dose-frequency requirement for carbamazepine (CBZ) in children was investigated using serial saliva samples to determine the daily fluctuation in drug levels. Mixed saliva was collected from 6 children (aged between 6 and 13 years) in a steady state, on each of two different dose-frequency regimens of once to 3 times daily, with a constant total daily dose. Increasing the dose-frequency resulted in smaller fluctuations in saliva concentration and a shorter time with levels outside the therapeutic range. Toxic features and convulsions appeared to be related to peak and trough concentrations. There was no apparent relationship between the total dose and the mean saliva concentration. The saliva CBZ half-lives in 2 children were 7·3 and 12·7 hours, and the apparent volumes of distribution (saliva) were 1·6 and 1·5 l/kg respectively. Saliva CBZ concentrations are an efficient and convenient means of tailoring individual dosage, and can be used to provide the pharmacokinetic data that rational prescribing demands.

Plasma level monitoring of anticonvulsant drugs in the management of convulsive disorders is being used increasingly (Kutt and McDowell, 1968; Kutt and Penry, 1974). The practice is now routine in most centres for phenobarbitone and phenytoin, for which established therapeutic ranges exist. For carbamazepine (CBZ), a therapeutic plasma concentration range in adults has been suggested from studies relating plasma levels with clinical effects (Morselli and Frigerio, 1975; Troupin *et al.*, 1975).

Saliva drug levels as a substitute for plasma levels have been shown to be useful for some anticonvulsant drugs in adults (Schmidt and Kupferberg, 1975; Troupin and Friel, 1975; Reynolds *et al.*, 1976), and for CBZ in children (Bartels *et al.*, 1977; Rylance *et al.*, 1977). The saliva levels of phenytoin, phenobarbitone (after correcting for saliva pH), and CBZ are similar to the concentrations of the free or unbound drug in plasma water (Schmidt and Kupferberg, 1975; Troupin and Friel, 1975; McAuliffe *et al.*, 1977), and may therefore be of greater therapeutic significance than the plasma concentration.

Some drugs are eliminated more rapidly by children than by adults (Svensmark and Buchthal, 1964; Borofsky *et al.*, 1972; Chang *et al.*, 1972), and the half-life of CBZ in 3 children receiving long-term treatment was reportedly shorter, 7·3–18·9 hours (Rane *et al.*, 1976; Rylance *et al.*, 1977), than in adults, 16·4–36·5 hours (Eichelbaum *et al.*, 1975; Faigle *et al.*, 1976). One consequence of this is that similar dosage produces lower steady-state drug levels in children than in adults (Morselli *et al.*, 1975; Monaco *et al.*, 1976). In addition, faster drug elimination would be expected to produce greater fluctuations in drug levels in children on a similar dose-frequency regimen as adults. Because of this and other pharmacokinetic factors, the dose-frequency regimens recommended for use in adults may be inappropriate for use in children.

In this study, the influence of dose-frequency on saliva CBZ levels was determined in a group of children.

Methods

Six children aged between 6 and 13 years attending the outpatient clinic of Ninewells Hospital, Dundee, were studied; approval was granted by the local hospital ethical committee. All children had received treatment with CBZ for at least 12 weeks before the study began, 3 receiving CBZ alone, and 3 receiving either phenytoin or ethosuximide in addition to CBZ.

University of Sheffield
G. M. BUTCHER, medical student

Mixed saliva was collected after stimulation with citric acid and flavouring (Bacon *et al.*, 1978) at approximately hourly intervals from 0900 to 2300 hours and from 0600 to 0900 hours the next day, the children spending the night in hospital. This procedure was carried out twice for each child. The total daily dose remained constant each time, but the dose-frequency was changed so that 2 children received CBZ once daily on the first occasion and twice daily on the second, and the other 4 received the drug two- and three-times daily (Table 1). The approximate times of CBZ administration were: once daily 0900 hours; twice daily 0900 and 2100 hours; thrice daily 0900, 1600, and 2300 hours. The children were maintained on each dose regimen for at least 6 days before saliva sampling, to enable a steady state to be reached.

Proprietary CBZ tablets were used except in Cases 4, 5, and 6 on thrice-daily regimens, when part of each dose was given as powdered proprietary tablet. To avoid contamination of the initial samples by CBZ retained in the mouth, the children swallowed water to rinse their mouths and brushed their teeth.

Saliva samples were stored at −20°C until assayed for CBZ by a modification of the method for serum described by Least *et al.* (1975). 2 ml saliva were added to a 10 ml glass-stoppered tube containing 5 ml chloroform, 1 ml 0·5 M sodium hydroxide, and 0·1 ml codeine in chloroform, 268 μmol/l (internal standard). The mixture was shaken vigorously for 10 min and the aqueous layer was removed and discarded. The organic layer was transferred to a tapered glass-stoppered tube and evaporated to dryness under nitrogen at 45°C. The sides of the tube were washed with 0·5 ml chloroform and evaporated as before. The residue was dissolved in 10 μl dry pyridine and 20 μl N,O-bis-(trimethylsilyl)-acetamide, incubated for 30 min at room temperature, and 1 μl aliquots injected into the GLC column. A Pye 104 gas chromatograph with dual flame ionisation detectors was used. The glass columns were 2 m × 4 mm in diameter, packed with 3% OV17 on Gas Chrom Q 100/120. Operating conditions were: injection port 300°C, oven 240°C, detector 300°C, nitrogen 50 ml/min, hydrogen 50 ml/min, air 250 ml/min. The sensitivity of the assay enabled the determination of CBZ down to 2 μmol/l. The mean coefficient of variation of the method over the concentration range 2–70 μmol/l was 3·5%.

The area under the CBZ concentration-time curve (AUC) was calculated for one dose interval (τ) for each child on each regimen using the trapezoidal rule. The mean steady-state saliva CBZ concentration ($\bar{C}_{ss}S$) was then calculated from the relationship, $\bar{C}_{ss}S = AUC/\tau$.

The daily fluctuation in saliva drug levels was expressed as a percentage thus:

$$\text{Fluctuation} = \frac{(\text{Highest} - \text{lowest concentration})}{\bar{C}_{ss}S} \times 100\%$$

The first-order elimination rate constant (k) in Cases 1 and 2 receiving the drug once daily was obtained from the regression line fitted to the logarithm of the saliva concentration versus time curve by the method of least squares.

Clearance (C), the apparent volume of distribution (Vd_{ss}), and the saliva half-life ($t\frac{1}{2}$) were calculated from the saliva data using the equation:

$$\bar{C}_{ss}S = \frac{F \,.\, D}{k \,.\, Vd_{ss} \,.\, \tau}$$

where D is the dose given at each time interval (τ), $C = k \,.\, Vd_{ss}$, $t\frac{1}{2} = 0{\cdot}693/k$, and F = fraction of dose absorbed, assumed to be unity.

Results

The 24-hour saliva CBZ concentration profiles of the 6 children on each regimen are shown in the Figure. The therapeutic range in saliva (5·5–15 μmol/l) was derived from the reported saliva/plasma

concentration ratio in children (Rylance *et al.*, 1977), and the recommended plasma concentration range in adults (Morselli and Frigerio, 1975; Troupin *et al.*, 1975).

The saliva levels peaked at between 1 and 6 hours, and in Cases 1, 2, 4, and 5, two peaks were observed. There was no contamination except in Case 3 on a twice-daily dosage regimen (Figure). The greatest fluctuation was found in Case 2 receiving CBZ once daily, and the smallest fluctuation in Case 3 on three doses a day (Figure). In all children, increasing the frequency of drug administration resulted in smaller fluctuations in saliva concentration. Frequent drug administration also resulted in a shorter time being spent with saliva levels outside the therapeutic range.

Both children on a once-daily regimen had saliva concentration fluctuations >160% of the mean steady state (Table 1). Increasing the frequency of drug administration to twice daily reduced the fluctuation to <75%. In the 4 other children, the fluctuation fell from 60–213% on twice-daily dosage to 38–75% on thrice-daily dosage.

The mean steady-state saliva concentrations resulting from the two dose regimens in each child, were similar in 4 children and in only 2 (Cases 4 and 5), was the difference >1 µmol/l (Table 1). There was no apparent correlation between the mean steady-state concentration and the total daily dose in any child.

Assuming complete bioavailability, the mean (±SD) saliva clearance of CBZ in the children on twice-daily dosage was 0·398 ± 0·167 l/kg per hour. The saliva CBZ half-lives in Cases 1 and 2 receiving the drug once daily were 7·3 and 12·7 hours, and the apparent volumes of distribution (saliva) for CBZ in these children were 5·78 and 6·12 l/kg respectively.

Toxic features were observed in 2 of the 6 children. Case 1 was ataxic about midday and was often sleepy by midafternoon when receiving CBZ once daily, and Case 3 became dizzy in the early afternoon on twice-daily doses.

None of the children had convulsions during the study period and 3 children had been convulsion-free for the previous 9 months. Two patients had each had one convulsion during the preceding month on their usual dose-frequency regimen, Case 5 at 0800 hours on twice-daily CBZ, and Case 6 at 2300 hours also on two doses a day. Case 4 had had convulsions at approximately monthly intervals during the previous 9 months at varying times of the day, on twice-daily administration.

Discussion

Minimum plasma concentrations and therapeutic ranges for CBZ have been suggested for adults, and the therapeutic concentration range in saliva adopted in this study was derived from these (Morselli and Frigerio, 1975; Troupin *et al.*, 1975), and from the saliva/plasma CBZ ratio in children (Rylance *et al.*, 1977). The mean steady-state saliva concentrations were within this range for all but one child (Case 5), and as expected, the frequency of drug administration did not influence concentration. The higher concentration in Case 5 receiving CBZ three-times daily was possibly a result of the greater bioavailability of the powdered drug used for him, although this was not observed in Cases 4 and 6 who also had part of their thrice-daily doses given in the powdered form.

Although the mean saliva CBZ concentrations indicated that the children were well controlled, there was considerable fluctuation about the mean. The concentrations rose steadily after drug administration reaching peak levels within 1–6 hours in all children, except for Case 3 on twice-daily dosage, in whom the concentration rose immediately after drug administration due to contamination by unabsorbed drug. Contamination was not observed at other times, nor was it observed in the other children. In 4 children the initial peak was followed by a short decline in concentration before peaking again.

The saliva clearance of CBZ was greater than that reported in adults (Westenberg *et al.*, 1978), and together with the two saliva CBZ half-lives which were similar to the plasma half-lives reported for children by Rane *et al.* (1976), indicate that children metabolise CBZ more rapidly than adults do.

A shorter CBZ half-life in children would be expected to produce a greater fluctuation in drug level than in adults, and indeed large variations in saliva concentration were observed in the children receiving the drug once or twice daily. Administration of CBZ thrice daily reduced the fluctuation in saliva drug levels, but large differences between peak and trough levels were still seen in 2 children (Cases 4 and 5). Although the CBZ concentration at the site of action will probably vary to a lesser extent than in plasma or saliva, large fluctuations in saliva will obviously reflect an increased risk of toxicity and/or convulsions. Two of the children in this study (Cases 1 and 3) showed toxic effects when saliva drug levels were at their peak and above the therapeutic range, and convulsions had occurred in two children (Cases 5 and 6) in the preceding month when receiving CBZ twice daily. The seizures occurred just before drug administration when the levels were presumed to be at their lowest.

Johannessen *et al.* (1976) found no direct relationship in adults between the frequency of drug administration and the daily fluctuation in serum levels. However, sampling was probably not frequent enough to detect change in fluctuations arising from the different dose-frequency regimens.

The data from our study suggest that children require more frequent doses of CBZ than do adults. Certainly, once-daily administration results in too great a fluctuation in concentration. Frequent administration may lead to reduced patient compliance, and can prove difficult if the child needs to take the drug during school hours. As many convulsions occur at night (Gibberd and Bateson, 1974), and this is the longest dose interval, it may be possible to improve control by giving a larger dose in the evening.

Single saliva CBZ determinations in children give a poor estimate of the mean steady-state concentration. This is demonstrated when the mean steady-state concentrations obtained for 5 of the children in this study are compared with single outpatient determinations carried out in the same children at random times while on the same dose-frequency regimens (Table 2). The outpatient values differ markedly from the mean steady-state levels.

Serial saliva samples are easily obtained from children of at least 4 years of age, and also from younger children if saliva flow is stimulated and a mucus extractor used (Bacon *et al.*, 1978), but because of possible contamination, care must be

taken in obtaining samples and interpreting their values in the period shortly after drug administration. Saliva concentration profiles are a convenient and effective means of assessing CBZ dose regimens in individuals, and it may be possible to use a similar approach for other anticonvulsant drugs.

Osteoid osteoma and benign osteoblastoma in childhood

J. A. BLACK, R. K. LEVICK, AND W. J. W. SHARRARD

The Children's Hospital, Sheffield

SUMMARY Three cases of osteoid osteoma and one of benign osteoblastoma in children are described. The main complaint was severe pain which was worse at night; it was relieved by aspirin or other analgesics. The diagnosis was made on clinical and radiological grounds and was confirmed on histological examination of the central nidus removed at operation. The pain was relieved in the patients with osteoid osteoma, and it was very much less after operative removal of the benign osteoblastoma. Both conditions are probably variations of the same disease process, depending on the anatomical site and the type of bone affected.

Osteoid osteoma was described as a clinical entity in 1935 by Jaffe, and then more fully by Jaffe and Lichtenstein (1940). In 1932 Jaffe and Mayer reported a patient in whom the disease differed somewhat from osteoid osteoma, and Dahlin and Johnson (1954) further described such cases and used the term 'giant osteoid osteoma'. The term benign osteoblastoma was introduced by Jaffe (1956) and Lichtenstein (1956) independently to differentiate this condition from osteoid osteoma. Since then numerous reports on both conditions have appeared, mainly in orthopaedic and radiology journals. In our experience children with these conditions are referred about equally to general paediatric and orthopaedic clinics. Nevertheless the clinical picture, which is similar in both osteoid osteoma and benign osteoblastoma, appears to be unfamiliar to many paediatricians. It was for this reason, and also because of the inherent difficulty in making the diagnosis, that we describe our experience with three patients with osteoid osteoma and one with benign osteoblastoma seen in Sheffield during the last 12 years.

Case reports

Case 1. Osteoid osteoma, left femur. This boy was born on 2 October 1958 and was first seen at the orthopaedic clinic at age 7½ years with a history of pain in the left thigh and a limp for a year. The pain was not constant and was relieved by aspirin. An *x*-ray showed irregular sclerosis of the medial side of the upper half of the shaft of the left femur; there was a faint oval translucent area at the level of the lesser trochanter, which was confirmed on tomography. A radiological diagnosis of osteoid osteoma was made (Fig. 1).

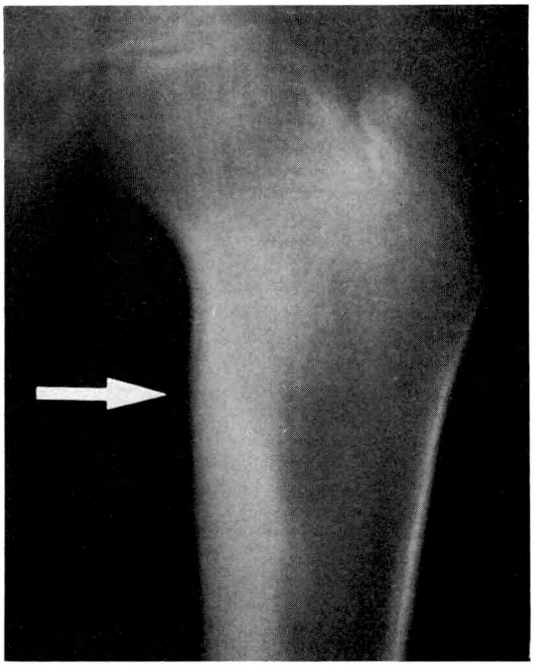

Fig. 1 *Case 1. Osteoid osteoma: sclerosis of medial side of femoral shaft and faint oval translucency at level of lesser trochanter.*

The Children's Hospital, Sheffield
J. A. BLACK, consultant paediatrician
R. K. LEVICK, consultant radiologist
W. J. W. SHARRARD, consultant orthopaedic surgeon

A small piece of bone was removed from the upper part of the femur but this did not show any histological evidence of osteoid osteoma. The pain was relieved for a short time but returned when he started walking. Two months later, further *x*-rays showed that the lucent area was still present; the pain was now very severe. At age 8 years he was readmitted for observation but did not appear to have any pain. One month later he was having to take 'up to 3 aspirins' daily. Further *x*-rays and tomography again suggested osteoid osteoma, and the femur was explored; this was nearly one year after his first visit to the hospital and 2 years after the onset of symptoms. On this occasion several fragments of bone were removed. One of these contained a nidus of irregular, partially calcified osteoid trabeculae separated by loose vascular connective tissue containing osteoblasts and osteoclasts, and bounded by dense lamellar bone. The appearance was consistent with the clinical diagnosis of osteoid osteoma. After this operation the boy was free from pain.

He remained well until October 1973, when at age 15 years, he complained of being always tired; he was very pale. Hb was 7·6 g/dl and blood film showed pronounced iron deficiency anaemia. He admitted that he had taken aspirin since his original trouble and that he was now taking it for headaches. His urine showed a faint purple coloration with Phenistix, and plasma salicylate level was 6 mg/100 ml (0·43 mmol/l). He was readmitted (J.A.B.) for further investigation. Apart from extreme pallor, no abnormality was found except that his stools showed a positive result in a test for occult blood. Barium swallow and follow-through radiological examination were normal. He was given ferrous sulphate tablets and returned home. Six weeks later Hb was 11 g/dl; the ferrous sulphate was finally stopped 3 weeks later when Hb was 13·8 g/dl. He felt well; there was no wasting of the thigh, and knee and ankle jerks were normal on both sides.

This case shows how difficult it is to localise the lesion at operation, in spite of clear radiological evidence of its existence. Aspirin dependence is a hazard to which people with osteoid osteoma are particularly prone, and there is no doubt that taking aspirin regularly for a long period caused severe iron deficiency anaemia from gastrointestinal bleeding.

Case 2. Osteoid osteoma, right femur. This boy was born on 18 March 1962 and referred to one of us (J.A.B.) at age 10 years with a 4-month history of pain in the right leg. The pain was not continuously severe but was worse at night, waking him at about 2 a.m.; it was relieved by aspirin and he had been taking one tablet each night for the previous 2 months. He had also been noted to limp occasionally and for one month his right leg had been getting thinner.

There was 2·5 cm of wasting of the muscles in the right midthigh, and knee and ankle jerks were reduced on the right side; there was also slight wasting of the right gluteal muscles. No muscle weakness or sensory loss was detected. A lumbar puncture showed no evidence of block, and the CSF was normal. The only radiological abnormality was a thickening of the cortex at the level of the lesser trochanter (Fig. 2).

He was referred to the orthopaedic department (W.J.W.S.); there was some tenderness of the upper half of the right femur and further *x*-rays of the femur with different degrees of rotation confirmed the cortical thickening in the upper half of the shaft; there was no evidence of a lucent central lesion after tomography, but osteoid osteoma was considered likely. He was readmitted to hospital and a block of bone at the site of the cortical thickening was removed. The tissue contained a central lesion which was histologically similar to that described in Case 1 and was typical of an osteoid osteoma; his pain was completely relieved. The total duration between the onset of symptoms and operation was 8 months. 10 months after the operation he was free

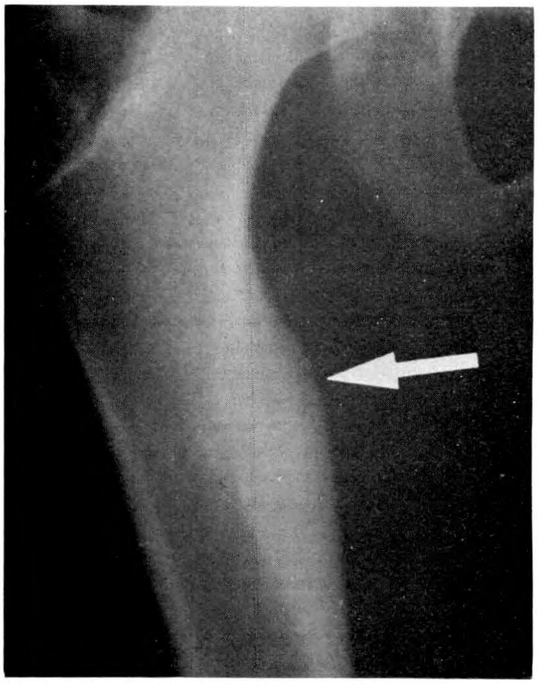

Fig. 2 *Case 2. Osteoid osteoma: sclerosis and thickening of the cortex at level of lesser trochanter.*

of symptoms; there was no wasting of the thigh, and his knee and ankle jerks on the right side were normal.

The wasting and reduced reflexes at first suggested a neurological lesion, but the radiological evidence strongly suggested an osteoid osteoma although a lucent area was never detected by radiography.

Case 3. Osteoid osteoma, left tibia. This girl was born on 24 October 1964 and referred at age 4½ years. She complained of a cramp-like pain in the left leg and a limp for the previous 2 months. The pain was particularly severe at night and was relieved by aspirin. There was slight wasting (2 cm) of the left thigh and calf muscles, with diminished muscle power in the left leg. The left ankle jerk was slightly diminished compared with the right side. *X*-rays showed cortical thickening of the posterolateral aspect of the lower tibial shaft (Fig. 3). There was a small lucent area which appeared to be deep to the sclerosis, and the diagnosis of osteoid osteoma was suggested.

She was admitted in May 1969 and at operation, using radio-opaque markers, a typical osteoid osteoma was removed; the diagnosis was confirmed histologically. The pain was completely relieved.

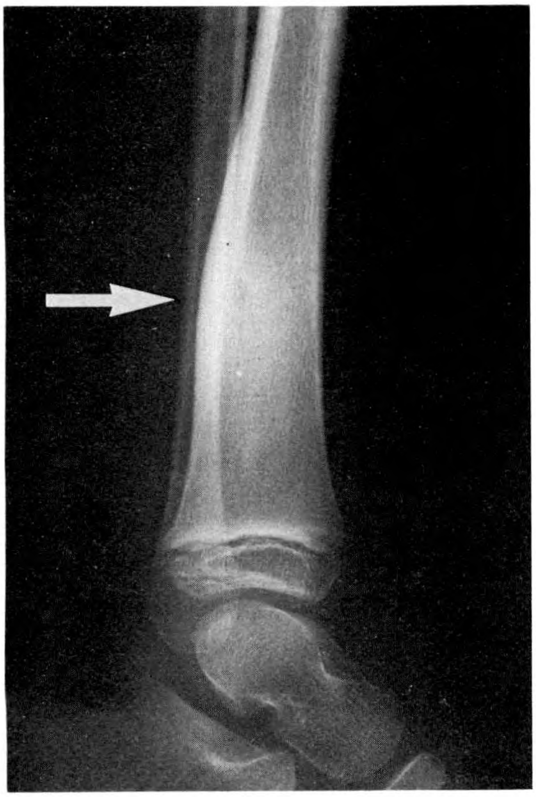

Fig. 3 *Case 3. Osteoid osteoma: sclerosis and thickening of the posterolateral part of the cortex of left tibia, with a small translucent area.*

Case 4. Benign osteoblastoma, right ischium. This boy was born on 4 December 1958 and, apart from lobar pneumonia at age 11 years, he had been well until he developed an aching pain in his right upper thigh at 13 years. He was seen at a paediatric outpatient clinic (J.A.B.) and was found to have 2 cm of wasting of the right thigh and 1·5 cm of wasting of the calf, with diminished knee and ankle jerks on the right side; there was a doubtful area of reduced sensation to pin pricks on the front of the right thigh.

Because of the possibility of compression of the right femoral nerve an IV urogram was done which showed an indentation of the bladder by a soft-tissue mass on the right side of the pelvis, and some sclerosis and thickening of the right ischium (Fig. 4). The ESR was 21 and 48 mm/in 1st hour. The right side of the pelvis was explored by an anterior approach; the right levator ani was bulkier than normal. A small piece of bone removed at operation showed no abnormality. The pain remained unchanged and he started taking paracetamol to relieve it. After 6 months' observation as an outpatient there was no improvement and he became a thin worried boy. He was referred to orthopaedic outpatients department (W.J.W.S.) where further *x*-rays, including tomograms, showed an area (1·5 cm in diameter) of lucency in the upper part of the right ischium. A Brodie's abscess was considered probable. He was readmitted and at exploration of the ischium an area of soft bone was scooped out. The histological appearance of the tissue removed was similar to that described in Case 1, except that the connective tissue separating the osteoid trabeculae was somewhat less vascular.

After operation his pain was almost completely relieved. He was last seen in 1973 (aged 14·8 years) when he still complained of slight pain: there was now only 0·6 cm of wasting of the right thigh, and knee and ankle jerks were equal on both sides. He was a cheerful boy and had gained 8 kg since the operation.

Discussion

Osteoid osteoma is twice as common in boys as in girls, with a maximum age incidence of between 10 and 25 years, and extremes from 1½ and 60 years (Poulsen, 1969). The presenting symptom is pain which is sometimes intermittent at first but later becomes continuous. The pain may vary in intensity and is characteristically worse at night. It has been

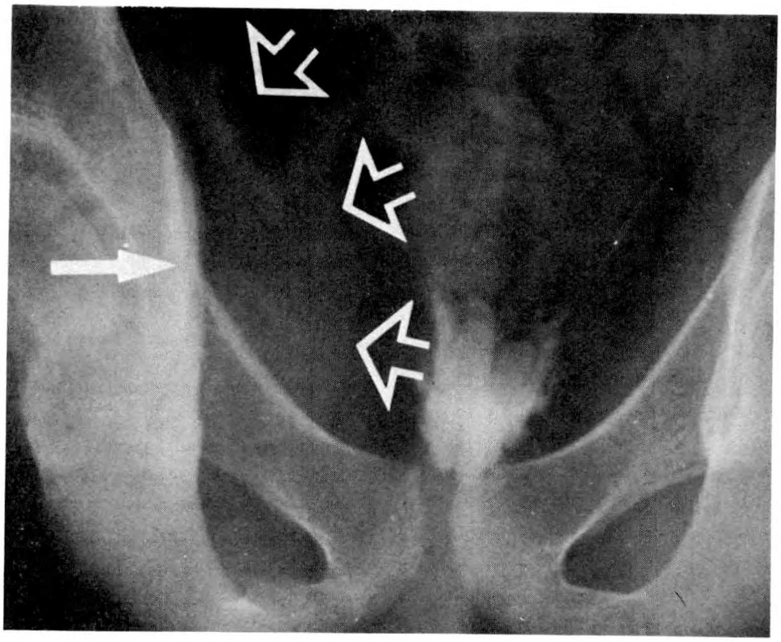

Fig. 4 *Case 4. Osteoblastoma: intravenous urogram showing indentation of bladder on right side (open arrows) with sclerosis and thickening of ischium.*

described as aching or boring, and patients usually obtain relief from such drugs as aspirin; this may cause dependence upon them (Case 1). Localisation is usually easy if a long bone is affected, but difficult if the lesion is in the upper part of the femur, the pelvis, or a vertebra. In order of frequency, the tibia and femur are most commonly involved, followed by the tarsal phalanges and the vertebrae, but almost any bone can be affected with the possible exception of the maxilla and facial bones. Lesions in the mandible (Flaherty *et al.*, 1956) and skull (Munk *et al.*, 1960) are rare. Epiphyseal lesions are rare but Sherman (1947b) described a patient with a lesion in the epiphysis of the great trochanter. Occasionally the pain is referred from the lumbar spine to the abdomen or leg, from the lesser trochanter to the knee, or proximally from the tibia to the hip (Golding, 1954), or thigh (Vaughan-Jackson, 1950). Very rarely the lesion is painless and presents as a swelling (Lawrie *et al.*, 1970). Other symptoms depend on the site of the lesion; if the shaft of the femur or tibia is affected there may be a limp, with wasting of muscles of the thigh, accompanied by loss or depression of knee and ankle jerks (Cases 1, 2, and 3). Rushton *et al.* (1955) found a positive Lasègue's sign in two cases with lesions of the femoral shaft, and one patient with loss of sensation to pain and touch over the anterolateral part of the thigh. Vertebral lesions may cause scoliosis, particularly in children and adolescents (Freiberger, 1960; Poulsen, 1969). In lesions near the elbow joint there is loss of flexion and extension with preservation of pronation and supination, and osteomyelitis may be suspected (Marcove and Freiberger, 1960). Szepesi *et al.* (1972) described two children with lesions in the great trochanter and femoral neck who had flexion contractures at the hip joints, and Johnson (1955) reported two patients with intracapsular lesions of the femoral neck in whom there was a chronic synovitis with fluid in the joints and infiltration of the synovial membranes with round cells. In young children deformity caused by uneven bone growth may develop if the lesion is near an epiphyseal plate (Ponseti and Barta, 1947), and in some cases the affected limb is longer than the normal one. Physical signs are varied; wasting rarely occurs except in the thigh or calf but a clinically evident effusion into an adjacent joint has been described (Sherman, 1947a; Spence and Lloyd-Roberts, 1961) and, particularly at the wrist and ankle, a nearby bone may show hyperostosis (Morton and Bartlett, 1966) or osteoporosis. Locally there may be exquisite tenderness and a slight increase in temperature. In areas easily accessible to palpation, thickening of the bone may be detectable. When a terminal phalanx is affected the whole finger end is swollen and dusky red, with excessive sweating and hypertrophy of the nail, and premature fusion of the phalangeal epiphyses has been observed (Rosborough, 1966). A lesion in a metatarsal bone may be mistaken for a march fracture (Kallio, 1963).

The clinical diagnosis of osteoid osteoma is notoriously difficult; the interval between the onset of symptoms and a correct diagnosis is seldom less than 6 months and it may be many years; it is not surprising, particularly in adults, that the depression, insomnia, and loss of weight produced by the long-continued pain often result in a diagnosis of hysteria or psychoneurosis. A limp, with wasting and reduced, or absent, knee and ankle jerks, may suggest compression of the femoral nerve or lumbosacral plexus, a cord lesion, or protrusion of an intervertebral disc. Brodie's abscess (Szepesi *et al.*, 1972) may be considered on clinical and radiological grounds, particularly if the sedimentation rate is slightly raised, which can occur in osteoid osteoma. O'Hara *et al.* (1975) considered that Brodie's abscess and stress fracture of the tibia were likely to cause the greatest diagnostic difficulties. Other conditions which may have to be considered (Purcell *et al.*, 1952) are solitary cortical abscess of bone, chronic sclerosing osteomyelitis of Garré, solitary tuberculous lesion in the shaft of a long bone, Ewing's tumour or osteogenic sarcoma, and chronic synovitis in cases with an effusion into an adjacent joint. A central cavity does not occur in chronic sclerosing osteomyelitis, but is found in a chronic tuberculous lesion. In case of doubt culture of material from the central lesion and microscopical examination should settle the diagnosis. The two malignant bone tumours can usually be distinguished by their rapid progression and destruction of bone. Lindbom *et al.* (1960) and O'Hara *et al.* (1975) have shown by angiography that the central area of an osteoid osteoma is extremely vascular, while a Brodie's abscess has an avascular centre.

Radiologically the lesion can usually be seen as a well-defined area of dense sclerosis, with a diameter of $\frac{1}{2}$–1 cm, occasionally up to 2 cm. In the centre of the sclerosis is a lucent nidus, sometimes containing speckled areas of calcification which may be mistaken for sequestra (Munk *et al.*, 1960).

Tomography may be necessary to demonstrate the central lesion, particularly if there is a considerable amount of thickened sclerotic bone surrounding it and, in some cases, a central area cannot be defined at all (Case 2). If the lesion is near the surface of the cortex or just under the periosteum, the long bones, especially the cortical bone, will be much thickened. Conversely, thickening is less pronounced if the lesion is in spongy bone. The thickened cortical bone can easily be missed unless a number of views are taken with different degrees of rotation (Case 2). Purcell *et al.* (1952) pointed out that thickened layers of subperiosteal bone may produce an 'onion peel' appearance similar to that seen in Ewing's tumour.

Spontaneous cure may occur after many years (Vickers *et al.*, 1959) and increased calcification in the central area has been regarded as evidence of healing (Moberg, 1951; Golding, 1954). However, the only effective treatment is complete excision of the whole central lesion. Accurate localisation of the lucent central area at operation is often difficult and may require the placing of markers under radiological control. In most instances the removal of a block of bone surrounding the actual lesion is preferable to an attempt to shell out the nidus as a small piece of tissue may be left behind; packing with an autogenous bone graft is sometimes required. Incomplete removal is followed by a recurrence of pain which can be relieved only by a further operation. Other methods of treatment, including radiotherapy, are useless.

Histologically the central lesion consists of an area of highly vascular tissue with wide vascular spaces and thick-walled blood vessels. There is much osteoid tissue, in irregular seams, with numerous osteoblasts. Unmyelinated nerve fibres have been found in the central area (Chandler and Kaell, 1950; Sherman and McFarland, 1965; Byers, 1968; Schulman and Dorfman, 1970), mainly in relation to the blood vessels. The aetiology of osteoid osteoma is obscure. Trauma seems to play a part in some cases (Marcove and Freiberger, 1960; Rosborough, 1966), particularly in the phalanges. The cause of the pain is not fully understood, but Golding (1954) showed that the pain in a metacarpal lesion could be relieved by applying a pneumatic tourniquet, inflated above the systolic pressure, to the upper arm. Sherman and McFarland (1965) pointed out that bone itself is relatively insensitive to pain and that bone lesions normally cause pain only when the periosteum is affected. Osteoid osteoma, however, is painful right from the start, irrespective of its anatomical relationship to the periosteum. Sherman and McFarland suggested that the unmyelinated fibres found in the lesions are autonomic nerves which are stimulated by distension of the blood vessels, causing pain and also the vascular dilatation and sweating which have sometimes been noted (Chandler and Kaell, 1960; Rosborough, 1966). The cause of the muscle wasting and depression of reflexes is difficult to explain as the weakness of the affected muscles is slight and certainly not sufficient to affect the reflexes: nor in most cases is there any significant amount of disuse of the affected limb. The vascular symptoms are similar to those found in glomus tumours (Kohout and Stout, 1961; Laymon and Peterson, 1965) in which there is sometimes vasodilatation and increased sweating of an affected finger (Stabins *et al.*, 1937) similar to that seen in a few cases of osteoid osteoma.

Benign osteoblastoma was differentiated from osteoid osteoma by Dahlin and Johnson (1954) who at first used the term giant osteoid osteoma. In 1964 Lichtenstein and Sawyer reviewed reports and added a number of new cases. The age, sex incidence, and distribution of lesions in benign osteoblastoma are similar to those of osteoid osteoma, but the former occurs more often in spongy than in cortical bone. Pain is less severe than in osteoid osteoma and is less easily located. The lesion is generally larger (2·5–5 cm in diameter), less regular in shape, and there is more thickening of the surrounding soft tissue (Case 4). When a vertebra is affected there may be compression of the cord or roots (Lichtenstein and Sawyer, 1964). Radiologically, there is an expanding area of bone destruction, usually with a sclerotic margin; when the surrounding bone is perforated a soft tissue mass is formed which may be identifiable in *x*-rays (Case 4). The differential diagnosis is similar to that of osteoid osteoma but should also include giant-cell tumour, fibrous dysplasia, aneurysmal bone cyst, nonossifying bone fibroma, and eosinophil granuloma (Wellmer *et al.*, 1968). Angiography may be helpful in difficult cases, as in osteoid osteoma. Treatment is by excision. In benign osteoblastoma the osteoid tissue is less regularly arranged than in osteoid osteoma and there are more multinucleated cells in addition to the osteoblasts. It remains uncertain, however, whether the two conditions are completely separate or are variations of the same disease process. A third, apparently related condition with multiple lesions similar to osteoid osteoma has also been described (Schajowicz and Lemos, 1970). De Souza Dias and Frost (1974) regard all three conditions as osteoblastoma and suggest a classification according to site: cortical osteoblastoma, spongious osteoblastoma, periosteal osteoblastoma, and multifocal osteoblastoma. They considered that the radiological appearance depended on the site of the lesion; in compact bone in or near cortex (osteoid osteoma) there was considerable tissue reaction, while in spongy bone (osteoblastoma) there was relatively little reaction. Schajowicz and Lemos (1970) also pointed out that an insistence that these lesions are always benign is probably unjustified in our present state of knowledge.

We thank Professor J. L. Emery and Dr Gillian Batcup of the Department of Histopathology, Children's Hospital, Sheffield, for the reports on the sections.

Cushing's disease presenting with growth failure: clinical remission during cyproheptadine therapy

D. B. GRANT AND SHELIA M. ATHERDEN

The Hospital for Sick Children, and Institute of Child Health, London

SUMMARY A 14·7 year-old boy had almost complete suppression of growth as a result of mild pituitary-dependent Cushing's disease. There was complete clinical remission during treatment with cyproheptadine (12 mg/day) and this was maintained when treatment was stopped after 18 months.

There have been several reports of children with Cushing's disease in which the salient clinical feature has been retardation of growth (Copinschi *et al.*, 1969; Streeten *et al.*, 1975; Lee *et al.*, 1975; Solomon and Schoen, 1976). Such a patient is described who underwent complete clinical remission during treatment with the serotonin-antagonist cyproheptadine.

Case report

Clinical features. The patient was first seen at age 14·7 years because he had not grown during the previous 4 years. His parents had kept a record of his heights from age 1½ years, and this showed fairly abrupt cessation of growth between ages 10 and 11 (Fig. 1). At about this time he gained weight rather quickly and his appearance changed as his face became rounder. Pubic hair appeared at about 11 years but there was no further progression in pubertal development.

When he was 6 years he had a successful course of treatment with gonadotrophin for an undescended testis, and a hydatid of Morgagni was excised when he was 10. In all other respects his health had been normal and he had no other symptoms.

On examination he was short (142·3 cm) and slightly obese (40·4 kg), with a round face (Fig. 2). With the exception of moderate hypertension (BP 135/95 mmHg), and slight bilateral gynaecomastia with mild generalised hirsutism, there were no other abnormal findings. His testes were prepubertal (1–2 ml), but he had a moderate amount of pubic hair with some development of the penis and scrotum.

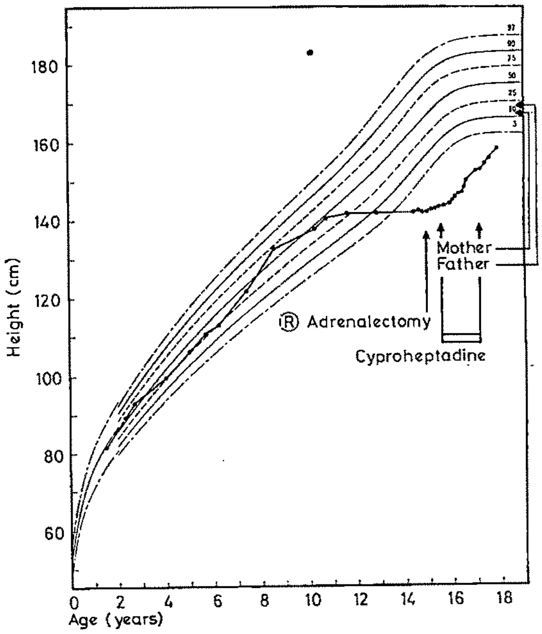

Fig. 1 *Patient's growth curve between ages 1½ and 18 years. Heights of his parents are also shown. Arrows show the timing of adrenalectomy and cyproheptadine therapy.*

Laboratory investigations. The initial investigations confirmed the clinical diagnosis of mild Cushing's disease. Urine free-cortisol was high at 565 nmol/24h

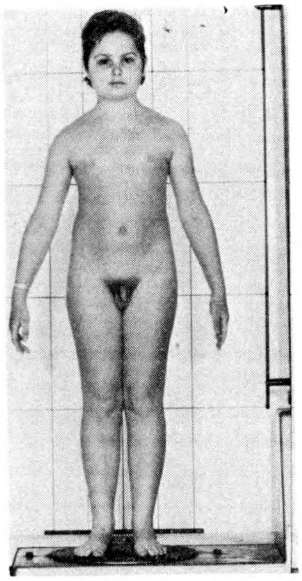

Fig. 2 *Appearance of the patient at age 14·7 years.*

(20·5 μg/24h), urine 17-hydroxycorticoid excretion was 82 μmol/24h (23·6 mg/24h), the cortisol production rate was raised at 83 μmol/m^2 per 24h; 30·6 mg/m^2 per 24h (normal 34·5 ± 7·9 SD), and the urine 17-oxosteroids were high at 44 μmol/24h (12·7 mg/24h). Plasma cortisol showed loss of normal circadian variation (260 nmol/l; 9·4 μg/100 ml at 0900h; 364 nmol/l; 13·1 μg/100 ml at 2300h). After 3 days' treatment with high-dose dexamethasone (2 mg 6-hourly) urine 17-hydroxycorticoids fell to 5·6 μmol/24h (1·6 mg/24h) and the 17-oxosteroids to 22.4 μmol/24h (6·4 mg/24h). However, plasma ACTH was undetectable (<32 ng/l) at times when the plasma cortisol ranged between 340 and 660 nmol/l (12·3 and 24 μg/100 ml). In view of the last finding, an adrenal tumour was suspected and an iodocholesterol scan was carried out. This showed apparently normal uptake by both adrenal glands, thus excluding the presence of a tumour.

Other endocrine causes of growth failure could be readily excluded. Plasma growth hormone rose from <1·0 to 25·4 mU/l 20 minutes after IV injection of 0·1 U/kg insulin. Plasma cortisol rose from 460 to 725 nmol/l (16·7 to 26·3 μg/100 ml) during this test. Plasma thyroxine was normal (121 nmol/l; 9·4 μg/100 ml), but a subsequent test with IV TRH (200 μg) showed an insignificant rise in plasma TSH from 1·0 to 1·6 mU/l after 30 minutes. Basal prolactin was normal (112 mU/l) and rose normally to 300 mU/l 15 minutes after TRH.

X-ray of the left wrist and hand showed a bone age of 11·4 years (Tanner *et al.*, 1975). Skull *x*-rays and IV-urogram were normal.

Clinical course. Two-stage adrenalectomy was planned and the right adrenal was removed when the patient was aged 15·1 years. The gland appeared normal in size (weight 6 g) and there was no evidence of hyperplasia on histological examination. In view of these findings, left adrenalectomy was deferred, and his adrenal function was reassessed after 2 months. Again, high urine free-cortisol levels were obtained (350–675 nmol 24h; 127–245 μg/24h). Serial estimation of plasma cortisol suggested episodic activity of his Cushing's disease. On one particular day, plasma cortisol varied from 860 nmol/l (31·2 μg/100 ml) at 0900 hours to 440 nmol/l (15·9 μg/100 ml) at 2300 hours, but the next day the levels were almost normal—280 nmol/l (10·1 μg/100 ml) at 0900 hours; 113 nmol/l (4·1 μg/100 ml) at 2300 hours. On both days plasma ACTH was low to normal (<22–58 ng/l).

During the next 6 months he grew very little and there was no appreciable advance in his bone maturation or pubertal development. When he was 15·8 years old, his height was 144·3 cm, and treatment with cyproheptadine (12 mg/day) was started. During the next 4 months he grew 1·2 cm, and after 6 months there was a definite increase in testicular size and his BP had fallen to 110/70 mmHg. At this time, normal values for plasma cortisol were found (80–225 nmol/l; 2·9–8·1 μg/100 ml) and his urine free-cortisol fell to 180–300 nmol/24h (65–109 μg/24h). A year after starting cyproheptadine his bone age was 12·6 years.

Treatment with cyproheptadine was stopped after 18 months when he was 17·3 years old. At this time his height was 153·7 cm, blood pressure 125/65 mmHg, further pubertal development had taken place (testicular volume 16–20 ml), and his gynaecomastia was unchanged. He has been followed up for 9 months since stopping cyproheptadine and has continued to grow normally without gaining weight; at age 18 years his height was 158·5 cm, his weight 45 kg, and his bone age 14·9 years. Urine free-cortisol levels have remained normal (90–182 nmol/24h; 33–66 μg/24h) since stopping treatment. Plasma cortisol estimated 3 months after stopping cyproheptadine showed very similar morning and late evening values: 210–300 nmol/l (7·6–10·9 μg/100 ml) at 0900 hours and 275–290 nmol/l (10–10·5 μg/100 ml) at 2200 hours, but 6 months later normal circadian variation appeared to be present: 240 nmol/l (8·7 μg/100 ml) at 0900 hours; 120 nmol/l (4·3 μg/100 ml) at 2200 hours.

Discussion

It is well known that excess secretion of cortisol in Cushing's disease greatly suppresses growth but only recently has it been widely appreciated that in some patients the disorder may be mild and, apart from growth retardation, there may be few of the classic clinical features (Lee *et al.*, 1975; Solomon and Schoen, 1976). In this case, there was some evidence that the disorder was episodic, as shown by the plasma cortisol profiles on two consecutive days. Plasma ACTH was at no time raised and at times it was undetectable, an unusual finding in pituitary-dependent Cushing's disease. Both these findings are probably in keeping with the observation that the resected right adrenal gland was normal in size and showed no histological evidence of hyperplasia. In the case reported by Lee *et al.* (1975), the adrenal glands were also normal on histological examination.

Our patient's normal growth hormone (GH) secretion is also unusual, as patients with Cushing's disease almost invariably have suppressed GH secretion (Copinschi *et al.*, 1969; Streeten *et al.*, 1975). This probably reflects the mildness of his disorder, as it appears that suppression of GH is largely related to high levels of plasma cortisol, rather than being due to a primary disturbance of hypothalamic or pituitary function (Tyrrell *et al.*, 1977).

In nearly all previously reported cases, patients with Cushing's disease presenting with growth failure were treated by bilateral adrenalectomy, and this was planned in our patient. Such treatment results in renewed growth but commits the patient to life-long replacement therapy with corticosteroids. There is also a significant risk that Nelson's syndrome (pituitary adenoma with hyperpigmentation) will develop later. Pituitary irradiation (Jennings *et al.*, 1977), or trans-sphenoidal exploration of the pituitary to remove an ACTH-secreting microadenoma (Tyrrell *et al.*, 1978), have also been successful in children with Cushing's disease.

As the disorder was mild in our patient a trial of cyproheptadine was given. This drug, which antagonises the effects of serotonin and suppresses ACTH secretion in normal subjects (Plonk and Feldman, 1976), was used successfully by Krieger *et al.* (1975) in the management of three adults with Cushing's disease. So far the use of this drug in children with Cushing's disease has been disappointing (Allgrove *et al.*, 1977; D'Ercole *et al.*, 1977), but in our case its use was associated with a pronounced acceleration of growth and bone maturation, and remission of hypertension. Spontaneous remission has been described in children with Cushing's disease (Putnam *et al.*, 1972) and this could account for our patient's improvement during treatment. However, we believe that a trial of cyproheptadine is indicated as the first line of treatment in patients with relatively mild Cushing's disease.

We thank Professor J. M. Tanner for referring the patient, Dr Lesley Rees for assistance with the ACTH assays, and Dr M. Savage for the bone-age estimations.

Short reports

Rectal paracetamol in small children with fever

SUE VERNON, CHRISTOPHER BACON, AND DORIS WEIGHTMAN

Departments of Child Health and Medical Statistics, Newcastle University, and Royal Victoria Infirmary, Newcastle upon Tyne

SUMMARY 37 febrile children aged between 3 months and 6 years were treated with paracetamol in a dose of 15–20 mg/kg by either oral elixir or rectal suppository. The rectal route was found to have an equal antipyretic effect and offers a practical alternative in those children for whom the oral route is not possible.

A high fever in a small child brings the risk of a convulsion as well as causing discomfort and increasing fluid loss. It has been shown that antipyretic drugs cool better than mechanical methods (Hunter, 1973), and that paracetamol and acetylsalicylate are equally effective (Colgan and Mintz, 1957; Eden and Kaufman, 1967). Paracetamol is often preferred because it has fewer adverse effects in therapeutic dosage and because accidental poisoning is less likely. The oral route is sometimes impractical—for example in a child who is convulsing, comatose, or vomiting—and absorption after oral ingestion may be impaired by the delay in gastric emptying that accompanies a severe illness (Heading *et al.*, 1973). At present no parenteral form of paracetamol is available. Previous work shows that paracetamol in rectal suppositories is well absorbed, but at a dosage of 10 mg/kg reduces fever in children less effectively than an oral elixir (Keinänen *et al.*, 1977). We therefore compared the antipyretic effect and practicability of the oral and rectal routes in small children using paracetamol in higher dosage.

Patients and method

40 children with rectal temperatures of at least 38·5°C were divided into two age groups (between 3 months and 2 years, and between 2 and 6 years) and randomly allocated within each group to either oral or rectal paracetamol. The oral preparation was the standard BPC elixir containing paracetamol 120 mg/5 ml, and the suppositories, which were made up in the hospital pharmacy, contained paracetamol 120 mg or 240 mg in 1 g of triglyceride base (Witepsol H15). Each child was given a single dose of 15 mg/kg paracetamol rounded to an appropriate multiple of 120 mg. Mean dosages ± 1 SD in the younger children were 20·2 ± 3·8 mg/kg (oral) and 19·7 ± 3·0 mg/kg (rectal), and in the older group 16·3 ± 3·3 mg/kg (oral) and 17·8 ± 2·4 mg/kg (rectal) (differences between dosages within each group were not statistically significant). Difficulties in drug administration were noted. Conditions were standardised as much as possible: the only clothing was nappies or pants, oral fluids were encouraged if appropriate, but no other means of cooling were used. The ambient temperature, which was monitored throughout the study period, was similar for each group of children. Rectal temperatures were recorded every 15 minutes for 3 hours by the same observer using an electric thermometer (IVAC 821).

Among the younger children, in the oral group 6 had upper respiratory tract infection (URTI), 3 bronchiolitis, 1 gastroenteritis, 1 mumps, and 1 encephalitis; in the rectal group 7 had URTI, 2 gastroenteritis, 1 bronchiolitis, 1 pneumonia, 1 urinary tract infection, and 1 encephalitis. Among the older children, in the oral group 5 had URTI, 1 mumps, 1 urinary tract infection, and 1 pyrexia of unknown origin; in the rectal group 4 had URTI, 1 measles, 1 cervical adenitis, and 1 roseola infantum. The groups were comparable in respect of duration of illness, state of hydration, and concurrent therapy, all these factors being recorded. The 2 children with encephalitis exhibited resistant hyperpyrexia and were therefore excluded from analysis, as was a third child in the younger oral group, who was found to have been given an extra dose of paracetamol in error. Paracetamol could not be given orally to 2 of the children initially allocated to this route, one because of vomiting and the other because of a convulsion; their inclusion in the rectal group did not bias the initial mean temperatures. There was no difficulty in giving the suppositories, even in children who had diarrhoea. One child (included in the analysis) extruded a partly-dissolved suppository 2 hours after its insertion.

Results

18 children (10 under 2, and 8 between 2 and 6 years) received oral paracetamol and 19 children (12 under 2, and 7 between 2 and 6 years) received rectal paracetamol. The initial mean temperatures of the younger children were 38·95°C (oral group) and 39·23°C (rectal group), and of the older children 38·89°C (oral group) and 38·99°C (rectal group). Within each age range the relationship between fall in temperature and time up to 3 hours from administration of paracetamol was highly significant ($P<0·001$) for both routes, and there was no significant difference between the routes. Figs 1 and 2 show the mean change from initial temperature at 15-min intervals in both age groups. Generally, the oral group of younger children cooled down more than the rectal group for most of the study period (Fig. 1), and the oral group of older children cooled down better at first but were later overtaken by the rectal group (Fig. 2); however these differences were not statistically significant. The mean fall in temperature of the younger children after 3 hours was 1·83°C (oral) and 1·66°C (rectal), and for the older children 1·63°C (oral) and 1·89°C (rectal) but there was a wider scatter in response among the rectal groups, possibly because of greater variability in absorption.

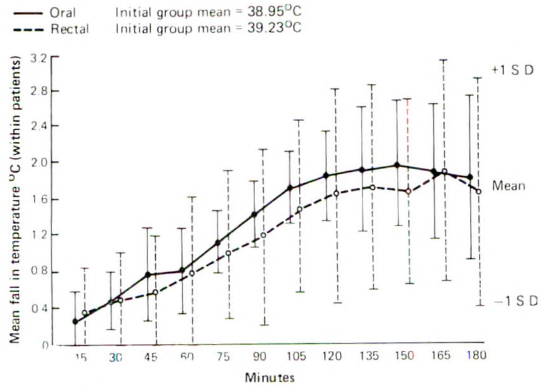

Fig. 1 *Mean change from initial temperature ± 1 SD at 15-min intervals for the children under 2 years on oral or rectal paracetamol.*

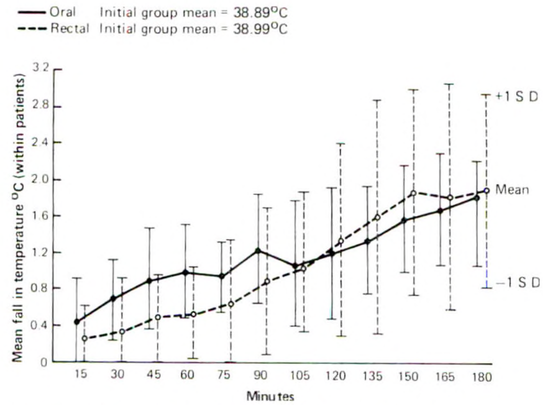

Fig. 2 *Mean change from initial temperature ± 1 SD at 15-min intervals for the children aged between 2 and 6 years on oral or rectal paracetamol.*

The younger children had generally reached their maximum fall in temperature by 150 minutes, whereas the temperatures of the older children, despite a smaller mean dosage of paracetamol, were usually still dropping at 180 minutes; this difference did not achieve statistical significance.

Discussion

Our results show that suppositories of paracetamol in small children in a dosage of 15–20 mg/kg offer an effective and practical alternative to an oral elixir. If both routes are available the oral may be preferred because of the greater consistency of response, but if oral administration is impossible the rectal route provides a good substitute. Paracetamol suppositories can be easily manufactured by a hospital pharmacy, but it would be helpful if they were widely available commercially so that they could be used at home. Their absorption characteristics may be improved if polyethylene glycol is used as base rather than triglyceride (Keinänen *et al.*, 1977).

We thank the Boots Drug Company whose grant made this study possible, IVAC (UK) for the electric thermometer, and our hospital pharmacy who made up the suppositories.

Acute infantile thrombocytosis and vitamin K deficiency associated with intracranial haemorrhage

J. LORBER, J. S. LILLEYMAN, AND E. B. PEILE

Department of Paediatrics, University of Sheffield, and Children's Hospital, Sheffield

SUMMARY A 5-week-old breast-fed girl presented unconscious and convulsing with heavily blood-stained CSF under increased pressure. This was associated with oozing from venepuncture sites, a grossly prolonged prothrombin time, and a raised platelet count. The prothrombin time became normal 18 hours after she had been given parenteral vitamin K and a transfusion of fresh plasma and red cells, but the thrombocytosis persisted. A moderate communicating hydrocephalus also remained and was treated, and one year later health and development appeared normal. The thrombocytosis resolved after a few weeks and has not recurred.

Thrombocytosis in infancy accompanying intracranial haemorrhage is rare and in the few cases that have been recorded was not associated with a clinical bleeding tendency or blood coagulation deficiency (Sanyal *et al.*, 1966).

We describe the case of a 5-week-old infant with an intraventricular haemorrhage who was found to have a high platelet count and was also noted to have a bleeding disorder with a grossly prolonged prothrombin time. This triad of intracranial bleeding, thrombocytosis, and possible late vitamin K deficiency has not been reported before.

Case report

The patient, the first child of healthy parents, was born after a normal pregnancy. The delivery was normal and her birthweight was 2·86 kg. Vitamin K was not given at birth. She was breast fed and in good health until age 5 weeks when she vomited and was irritable for 3 days, before becoming comatose. On admission to hospital she was unconscious, moaning, very pale, rigid, and had a tensely bulging anterior fontanelle. She also had two small bruises in the popliteal fossa and was seen to ooze excessively from venepuncture sites but there was no evidence of external injury.

Lumbar puncture showed blood-stained and markedly xanthochromic CSF under increased pressure. Subsequently, a ventricular tap also yielded heavily blood-stained CSF. Hb was 7·1 g/dl; WBC 14·3 × 10^9/l (differential counts showed a neutrophilia); and platelets 1154 × 10^9/l. The prothrombin time was grossly prolonged, as were partial thromboplastin and plasma recalcification times, but the thrombin time and concentration of fibrin/fibrinogen split products were normal.

Immediate transfusion of 50 ml fresh plasma and 90 ml stored blood was given together with 2 mg parenteral vitamin K; 18 hours later there was total correction of the prothrombin and recalcification times, with the partial thromboplastin time returning to normal in 42 hours. The platelet count, however, remained high at 900 × 10^9/l, and a further legacy of the event was a moderate, freely communicating hydrocephalus, which was treated with ventricular drainage and, subsequently, by isosorbide by mouth.

Platelet function studies were normal, and the thrombocytosis was last noted 4 weeks after presentation (760 × 10^9/l) but had disappeared 7 months later (340 × 10^9/l). The relevant haematological parameters are given in the Table.

Clinically the child has no apparent sequelae, and is well at the time of writing (2 years). Prothrombin time, partial thromboplastin time, and plasma recalcification time have apparently remained normal since correction after plasma and vitamin K on the one occasion, and the thrombocytosis has not recurred.

Table *Summary of haematological abnormalities after admission*

Time after admission	*Hb (g/dl)*	*Platelets (× 10^9/l)*	*Prothrombin time (British corrected ratio)*	*Partial thromboplastin time (ratio to control)*	*Fibrin degradation products (µg/ml)*
0	7·1	1154	>10·0	>10·0	<10
18 hours	11·1*	750	1·15†	1·4	—
42 hours	9·2	510	1·0	0·9	<10
4 days	10·2	900	—	—	—
13 days	10·4	1015	—	—	—
1 month	11·3	760	—	—	—
8 months	13·0	340	—	—	—

*After transfusion, †after vitamin K and fresh plasma.

Discussion

High platelet counts are rarely found in babies, and conditions associated with them have been reviewed (Addiego *et al.*, 1974). The thrombocytosis in this patient was discovered at the same time as a subarachnoid and intraventricular haemorrhage and a gross coagulopathy, and how these relate to each other is not certain. A likely sequence of events is that the coagulopathy allowed bleeding which provoked an unusually pronounced reactive platelet increase. If the high platelet count was the *cause* of bleeding, as paradoxically can occur in some myeloproliferative disorders, the coagulopathy would have to have been coincidental, which seems improbable.

Infantile central nervous system disease associated with thrombocytosis alone has been recorded by Sanyal *et al.* (1966) and Huttenlocher and Smith (1968) and has been implicated as being causally related (by precipitating cerebral thrombosis) as the high platelet count was seen to precede an acute hemiplegia in one case (Huttenlocher and Smith, 1968). In no previous report has a coincidental disorder of coagulation been noted.

Late vitamin K deficiency in infants has been described (Nammacher *et al.*, 1970; Cooper and Lynch, 1979), and while the evidence for its existence in our case is entirely circumstantial, it is hard to offer an alternative explanation for such rapid permanent *in vivo* correction of a clinically obvious bleeding tendency associated with a prolonged prothrombin time in the absence of intravascular coagulation. There was no reason to suppose that the production of liver coagulation factors was impaired from any other cause, but no estimation of protein induced by vitamin K absence was made, which would have helped to clarify this aspect.

Quite why this child should be lacking vitamin K is hard to say, as breast feeding is the only reason to suppose a deficient supply. It must be acknowledged that it is possible some other factor provided permanent correction of the observed and apparently acquired bleeding tendency, but to define such a factor is not possible.

We thank Dr B. L. Priestley for referring this infant to us.

Premature menarche without other evidence of precocious puberty

M. E. HELLER, JOHN DEWHURST, AND D. B. GRANT

Queen Charlotte's Maternity Hospital, and The Hospital for Sick Children, London

SUMMARY We describe 4 young girls with recurrent vaginal bleeding in the absence of other signs of precocious sexual development. Investigation showed low oestrogen levels in 2 of them, and basal gonadotrophins were in the upper part of the prepubertal range. We believe that the isolated early menstruation in these patients was possibly related to increased sensitivity of the endometrium to oestrogens.

Cyclical vaginal bleeding in the absence of other signs of secondary sexual development is rare and little has been written about the clinical and laboratory aspects of this condition. We describe 4 young girls seen at The Hospital for Sick Children because of recurrent menstrual bleeding; they had no other stigmata of precocious puberty or evidence of an underlying genital disorder.

Case reports

Case 1 (born 14.11.1960). When she was 10 months, this girl began to have episodes of vaginal bleeding which lasted for 2 or 3 days and recurred every 4 to 5 weeks. She had been born 2 weeks after the expected date of confinement, but her neonatal history and developmental progress were normal.

She was admitted to hospital at age 1·2 years for further investigation. Her height (80 cm) and weight (11·4 kg) were just above the 75th centiles. No abnormality was found on examination. In particular, there was no breast development or pubic hair, no abnormal skin pigmentation, and examination under anaesthesia (EUA) was normal with no adnexal masses. A vaginal smear taken at the time of bleeding showed immature epithelial cells, but a further smear taken 2 weeks later showed definite evidence of oestrogenisation. Bone age was appropriate for chronological age, the urine 17-oxosteroids were not raised (0·4 µmol/24h; 0·1 mg/24h), and a slight increase in urine gonadotrophins was found on bioassay (2·1 HMG 20A units/24h).

Vaginal bleeding continued fairly regularly until age 3·4 years and then it began to lessen, finally stopping at age 4½. Urine gonadotrophins were undetectable (<0·2 HMG 20A units/24h) when re-estimated by bioassay at age 3·2 years.

When she was 10·8 years, vaginal bleeding recurred and took place almost daily. Because of continued bleeding she was readmitted at age 11·3 years. At that time she had early breast development but no pubic hair. Her height and weight were on the 50th centiles, her bone age was slightly advanced (12·5 years), and a vaginal smear showed definite evidence of oestrogenisation. Urinary oestrogen excretion was in the early pubertal range (10·5 nmol/24h; 3 ng/24h), as was urinary luteinising hormone (LH) excretion (6·5 IU/24h). Skeletal survey showed no evidence of fibrous dysplasia.

At age 12·2 years, her menorrhagia stopped and her periods became more regular. Secondary sexual development proceeded normally. When last seen at age 14·3 her menses were regular, pubertal development was well advanced, and her growth appeared complete.

Case 2 (born 13.4.1973). This girl, who was born after a normal pregnancy, began to have vaginal bleeding when she was aged about 18 months. This occurred every 28 days and lasted for up to 7 days with occasional intermenstrual spotting. She complained of abdominal pain before the onset of each episode of bleeding, but was otherwise in good health.

She was admitted for investigation at age 3½ years. Her height (92·8 cm) and weight (13·4 kg) were on the 50th centiles. There was no palpable breast tissue or pubic hair, and the vulva appeared infantile. She had no abnormal skin pigmentation. Investigations showed that the bone age was slightly retarded (2 years) and no evidence of fibrous dysplasia was seen on *x*-rays of the skull and long bones. Urinary LH (2·9 IU/24h) and FSH (2·1 IU/24h) excretion were within the normal range for age, as were serum LH (2·0 mIU/l) and FSH (1·0 mIU/l). Plasma oestradiol was undetectable (<0·1 pmol/l; <0·03 pg/ml). EUA showed a small uterus with no adnexal masses, and cystoscopy was normal.

The patient had an episode of vaginal bleeding soon after the EUA, but when last seen at age 4·1 years there had been no further bleeding or other symptoms.

Case 3 (born 28.11.1974). This girl was seen when she was 2·9 years because of 7 episodes of vaginal bleeding since age 2·2 years. Her health and development until this had been normal. On examination, her height (89·6 cm) and weight (12·6 kg) were near the 50th centiles. No breast tissue was palpable and there was no pubic hair. The vulva appeared infantile and no pelvic masses were palpable on rectal examination. There was no abnormal pigmentation. Investigation at age 3·4 years showed a bone age between 3 and 3½ years and no evidence of fibrous dysplasia on skeletal survey. No hypothalamic or other brain abnormality was found on CAT. Her urinary LH excretion (1·1 IU/24h) and serum LH (1·0 mIU/l) were appropriate for her age, and there was no significant rise in serum LH after injection of 100 µg luteinising hormone-releasing hormone (LRH). In contrast, urinary FSH excretion was slightly raised (3·4 IU/24h) and after injection of LRH, there was a pronounced rise in serum FSH from 1·7 to 33·0 mIU/l after 60 minutes. Urinary total oestrogen excretion was 3·5 nmol/24h (1 ng/24h).

Case 4 (born 18.2.1975). This girl began having vaginal bleeding when she was 3 months; it occurred at intervals of between 30 and 32 days, lasted for 2 or 3 days, and was preceded by up to 10 days of irritability and feeding difficulties. She had been born 2 weeks after term, but her health and developmental progress had been normal. When she was older, she complained of abdominal pain before each episode of bleeding.

When she was 2 years she was admitted to another hospital where an EUA was normal. As her bleeding continued, she was referred to The Hospital for Sick Children for further investigation. When seen at age 2·9 years, her height (93·3 cm; 75th centile) and weight (13·4 kg; 50th centile) were normal. There was no breast development or pubic hair, and the vulva appeared infantile. Rectal examination was normal and there was no abnormal skin pigmentation.

Investigations showed a slightly retarded bone age (2 years), serum LH (2·8 mIU/l) and FSH (2·1 mIU/l) were in the upper prepubertal range. There

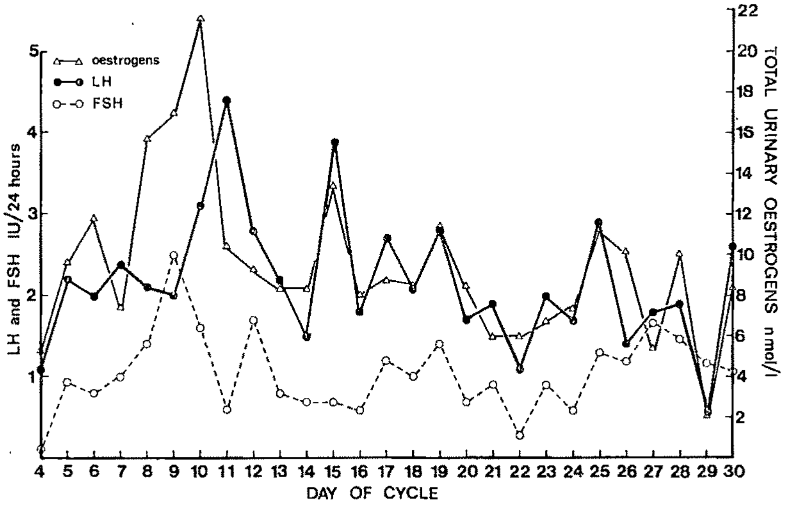

Figure *Urinary LH, FSH, and total oestrogen excretion from day 4 to 30 of a menstrual cycle (Case 4). A further episode of bleeding took place 7 days after the last collection of urine.*

Conversion: *SI to traditional units—urinary oestrogens: 1 nmol/l ≈ 0·27 ng/ml*

was no evidence of fibrous dysplasia on *x*-rays of the long bones.

Serial 24-hour collections of urine were carried out by the girl's mother at home. The collections were started on the 4th day after onset of bleeding and a further episode of bleeding took place 7 days after the collection period ended. The results for total urinary oestrogens, LH, and FSH excretion are shown in the Figure. While total urinary oestrogen excretion was generally low, an apparent peak of excretion took place on the 7th day of the collection (10th day of cycle). The next day, there appeared to be a small peak of LH excretion (4·3 IU/24h), with a possible further peak (3·9 IU/24h) 5 days later. Urinary FSH excretion was low throughout the period of collection.

Discussion

Our 4 cases are very similar to a case described by Blunck *et al.* (1967) in a review of transient sexual precocity. Their patient had recurrent menstrual bleeding which was not associated with other signs of secondary sexual development and she subsequently developed normally. In his textbook, Huffman (1968) described 2 such patients and referred to their benign clinical course. Similarly, our Case 1 menstruated fairly regularly between ages 10 months and 3·4 years and she subsequently had normal secondary sexual development after an initial period of menorrhagia. Our other 3 patients menstruated for between 1·2 and 2·7 years without other stigmata of precocious puberty, such as accelerated growth and bone maturation.

In a proportion of cases with precocious puberty, menstrual bleeding may be the first clinical manifestation. For example, Sigurjonsdottir and Hayles (1968) found that 5 out of 54 girls with precocious puberty presented with bleeding between ages 6 months and 1·9 years. Further evidence of secondary sexual development occurred within 2 months to 1·8 years.

Menstrual bleeding is often the first sign of precocious puberty in the McCune-Albright syndrome, in which it is associated with abnormal skin pigmentation and fibrous dysplasia of bone. While in none of our Cases 1–4 was there abnormal skin pigmentation, we have seen 2 girls with a forme-fruste of McCune-Albright syndrome and no abnormal skin pigmentation. The first of these girls started to menstruate at age 6 weeks and the second at age 5·9 years. Initial *x*-rays were normal in both girls and radiological evidence of fibrous dysplasia did not develop until ages 7 and 9 years respectively. It is therefore possible that fibrous dysplasia may later become apparent in Cases 1–4.

In at least one patient, a local genital lesion was initially suspected as the cause of vaginal bleeding. Although a vaginal foreign body may present with bleeding, this does not show the cyclic pattern described above and usually causes a purulent vaginal discharge, which was not present in any of our patients. Genital neoplasms—such as botryoid sarcoma or hormonally active ovarian tumours—are rare causes of vaginal bleeding in childhood and were excluded by physical examination in our patients. Ingestion of oestrogen was suspected as a cause of the bleeding, but this was denied by the girls' mothers. In addition, the episodic nature of the bleeding and the absence of breast development virtually exclude this possibility.

We have no good explanation for the early menstruation in our patients, but believe that it may be due to increased sensitivity of the endometrium to circulating levels of oestrogens which are too low to produce breast development. Certainly, the oestrogen values obtained in 2 of the patients were far below the levels found in normal ovulatory cycles. Case 4 apparently had a peak of urinary LH excretion on the 11th day of one of her menstrual cycles which was preceded by a peak of urinary oestrogen excretion on the previous day. The brisk rise in FSH after LRH stimulation in our Case 3 is surprising and is not in keeping with the very modest basal FSH levels found in 2 of the other cases. Further studies are obviously needed to establish whether this pronounced rise in FSH after LRH is a consistent feature in girls with early isolated menstruation.

We thank our colleagues for referring their patients for investigation.
